ORIGINAL LECTURES.

CASES ILLUSTRATIVE OF THE EFFICIENCY AND NON-EFFICIENCY OF DIGITALIS IN THE TREATMENT OF DIFFERENT STAGES OF VALVULAR DISEASES.

A Clinical Lecture,
delivered at the Philadelphia Hospital.

BY FREDERICK P. HENRY, M.D.,
VISITING PHYSICIAN TO THE HOSPITAL, ETC.

[Reported by W. A. NEWMAN DORLAND, M.D.]

GENTLEMEN: This patient is, as you see, a colored man about sixty years of age, who when admitted complained of intense dyspnœa, amounting to orthopnœa, in addition to which there were great feebleness and irregularity of the pulse, slight œdema about the ankles and legs, and some ascites—in fact, a general anasarca. At the time of his admission to the hospital, on November 18th, I could almost bury my fingers in the skin of the chest, so great was the œdema. This has now disappeared not only from this point, but also from the legs. Besides these symptoms there were signs of pulmonary congestion. The cause of this alarming array of symptoms was evident. There was no difficulty in detecting a systolic murmur over the mitral region, which was transmitted to the left so as to be heard at the anterior border of the latissimus dorsi muscle of that side. The time of its occurrence, the area of greatest intensity, and the direction of transmission indicated mitral insufficiency, with a certain amount of regurgitation into the left auricle and interference with the pulmonary circulation. The veins of the pulmonary system are destitute of valves and pursue a remarkably straight course, and hence in case of disease this anatomical peculiarity becomes a disastrous feature.

The symptoms in this case came on suddenly, although the lesion on which they depended was an old one. Whenever we are called upon to take charge of a case of acute disease, we should ascertain whether the attack originated *de novo* or whether it has for its foundation some chronic organic defect. It is unnecessary to mention how prognosis and treatment will vary according to the results obtained from such an examination.

This man tells us that on the day before his admission he was whitewashing a damp, cool cellar. Indeed, it was more than damp, for his feet and legs were immersed in cold water. There has been nothing inflammatory in the nature of his attack, as is indicated by his temperature-chart, which shows a curve persistently subnormal, with the exception that twice it exceeded the normal point and twice it reached the normal. Normally an antagonism exists between the venous and arterial circulations, the maintenance of which is essential to health. In disease this antagonism is destroyed. In this case the arteries gave up the struggle, their tension relaxed, and the whole circulation became of a venous type, as shown by the œdema and other symptoms.

The object of treatment, then, was to restore arterial tension, and this was done by the use of digitalis, which is still the best of the many cardiac tonics.

To-day I propose to say a few words concerning the action of this drug, illustrating my remarks by facts in the clinical history of this case. Results thus obtained are worth more than those obtained from dozens of experiments upon animals. So-called experimental therapeutics has often nothing to do with clinical therapeutics. To illustrate this point, the other day a friend of mine told me of his ineffectual attempts to kill a superannuated horse by prussic acid, and in a paper recently read before the College of Physicians a number of experiments were reported, one of which consisted in injecting beneath the skin of a dog, weighing fifteen pounds, thirty grains of quinine, equivalent in a man weighing two hundred pounds, to four hundred grains—a dose entirely impracticable. I hold that a clinical study of the action of drugs is more instructive than any number of experiments upon animals.

In a study of the present case, in the first place I would emphasize the fact that these symptoms arose suddenly and followed exposure to cold and wet, and that they promptly yielded to the administration of digitalis. This indicates that there are many healthy muscular fibres in the man's heart. Otherwise the digitalis would have had no effect on his condition, the first requisite to the successful action of the drug being the presence of healthy fibres in the heart. Are there any methods by which we may judge of the degree of degeneration to which the cardiac muscle has advanced? There are. In the first place, we are justified in inferring the presence of a certain amount of healthy muscular fibres if the first sound is relatively louder and more prolonged than the second. This opinion is corroborated if the apex-beat is clearly defined. Again, a distinct murmur can only be produced by a heart acting with considerable force. A faint murmur associated with other symptoms of cardiac failure is, therefore, more serious than a loud one. In such cases digitalis is indicated.

Another indication for the employment of digitalis, an indication distinctly present in this case, is a feeble, rapid, and irregular pulse. Attention was called to this by Withering, the first systematic writer on the use of the drug. Withering noticed that digitalis is much more efficient when the pulse is weak and feeble than when it is hard and regular. We also find a further indication for its employment in diminution of the urinary secretion, which was a very marked symp-

tom in this case, only 15 ounces of urine being passed in the first twenty-four hours after his admission. It subsequently increased to 33 ounces, 137 ounces, 89 ounces, and so on. There was a very slight amount of albumin in his urine, and this fact, taken in connection with the absence of casts, tends to exclude Bright's disease.

With reference to the action of digitalis in heart disease, we may divide the heart's action into three stages: the first, or stage of *eusystole*, when compensation is well maintained, and it is unnecessary to give digitalis; in fact, under such circumstances, the drug is useless and may even be injurious. Shortly after this stage the symptoms may change, and the second stage, that of *hypersystole*, follows. In this the heart is endeavoring to overcome the valvular defect, and in doing so is exhausting itself. It is making a greater effort than is necessary, and is becoming hypertrophied, as evinced by displacement of the apex-beat. There may be at this stage a sensation of fulness in the head, tinnitus aurium and insomnia. Here digitalis is decidedly injurious. The third stage of cardiac disease is a condition of *hyposystole*. This begins with dyspnœa on slight exertion, or even during ordinary conversation, a sure sign that the circulation is approaching the venous type.

A division of the heart's action into these three stages explains certain discrepancies of opinion with reference to the use of digitalis in cardiac disease. Thus Grisolle has stated that digitalis is contra-indicated in all forms of stenosis; while, on the other hand, Lelion, another Frenchman, maintained in his inaugural thesis exactly the reverse, viz., that digitalis was indicated in all cases of aortic stenosis. In 1877, Milner Fothergill, in a paper published in the *British Medical Journal*, adopted a view similar to that of Lelion, so far as aortic stenosis is concerned. In aortic stenosis, he says: "By exciting ventricular contraction more blood is enabled to be passed in a certain time, and thus equilibrium is maintained." Niemeyer, however, took an opposite view of this question. The same discrepancies exist in regard to stenosis of the mitral valve. Niemeyer recommended its use in this condition; while, on the other hand, Potain says that in mitral stenosis digitalis may be long dispensed with. Finally, Gubler has declared it to be entirely useless in lesions of the mitral valve, whether stenotic or regurgitant.

Can these statements be reconciled, and, if so, in what manner? Certainly not by impeaching the testimony of these men who were authorities in their time. By considering the different stages in which the drug was administered we can arrive at an exact result. Hence the division of cardiac disease into three stages: in the first of which digitalis is useless and may be injurious; in the second it is injurious, and in the third it is invariably beneficial if the degeneration of the muscular fibres has not proceeded too far.

Some valvular lesions are more benign than others. Thus, mitral stenosis is the least dangerous, according to Austin Flint, while others assert that mitral regurgitation is the most benign. According to all, sudden death is more apt to occur in aortic regurgitation than in any other form of heart disease, and some go so far as to say that it is the only form that is likely to terminate in sudden death. Cardiac lesions may exist for many years with no symptoms, the patient dying of another affection. In these cases digitalis is not required. The indication for the employment of digitalis depends upon the condition of functional activity of the cardiac muscle. If it is able to perform its function, digitalis is useless. On the other hand, if the heart is acting with unnecessary strength, to overcome the effects of the lesion, use drugs such as the bromides, morphine, and aconite, associated with a bland diet, in which the only animal ingredients are milk and eggs. In the stage of hyposystole some one of the many preparations of digitalis may be employed. In the case under consideration we gave two drachms of the infusion every three hours, until the urine was very decidedly increased in amount, the pulse strong and regular, and the dyspnœa had entirely disappeared. In prescribing digitalis do not be disappointed if you do not obtain immediate results. In this case the urinary secretion was not decidedly increased till forty-eight hours after his admission, when it rose to considerably more than one hundred ounces. We then stopped the digitalis and administered caffeine to maintain diuresis.

There are certain points connected with the action of this drug which by the inexperienced are at times thought to be the effects of the disease itself. For example, it sometimes renders the pulse very unstable, as in this case, in which slight exertion made it rapidly rise to a high point. Consequently the best effects of the drug are secured by keeping the patient quiet, not allowing him to sit up until the equilibrium is properly restored. When giving digitalis, compare the radial pulse with the cardiac beat. You will often notice that the latter is more rapid than the former. The heart is not strong enough to give rise to a beat at the wrist with every contraction, and sometimes this disproportion increases to two to one. This is supposed by some to be due to a separate contraction of the two ventricles. I reported a case in 1881 in which I think this condition existed. The sphygmogram showed two beats of the heart to one of the pulse, with a tracing which was taken over the heart.

The relative size of the two beats is what one would expect from the relative strength of the two ventricles. When we consider the arrangement of the cardiac muscular fibres, it seems almost impossible to have the ventricles acting asynchronously, but these cases show its possibility. This action of the heart has been attributed to the effects of digitalis, but the question is an open one. There is, however, a condition undoubtedly due to the action of digitalis. This is an irregularity of the heart called "*pulsus bigeminus*," two beats of the heart followed by a long pause, a condition which may continue for hours.

In this case the action of digitalis has been markedly successful. The patient has still signs of bronchitis, but there is no pulmonary œdema and no orthopnœa. The heart is acting with regularity, the murmur is present and stronger than on admission—a good sign. The urine is increased in amount and the appetite is good. Failure of appetite and other signs of digestive disorder are always present in the stage of failing compensation, so much so that "*cardiac dyspepsia*" is now recognized as a distinct morbid condition.

I now show you a case in which digitalis has been of

no use whatever, and in which we were obliged to abandon the administration. The patient is a white man, sixty years old, a native of Ireland, who was admitted April 21, 1890. When I first saw him he had pain in his chest, and on examination I found a murmur in the second interspace at the right border of the sternum, synchronous with the systole of the heart, and propagated along the arteries of the neck. There was no regurgitant murmur. If the semilunar valves are contracted you will find a murmur not only in the systole, but also a regurgitant murmur, that is, a "see-saw" murmur. If the murmur is systolic alone, with no trace of regurgitation, you will find the lesion in the aorta itself, as a rule, above the valve. In this case we have all the symptoms of angina pectoris, except that they do not occur in paroxysms. The pain radiates from the heart involving the right side as well as the left. It is a subacute or chronic case of angina. The condition of the heart was that of hypersystole—great force and rapidity of action, with a pulse of 100 per minute. Digitalis was doing no good or was actually injurious. We stopped its use and gave the patient one-eighth of a grain of sulphate of morphine, every three hours. He improved greatly under this. The other points in the case are of no special interest beyond a great tenderness of the liver from venous congestion. I would like you to bear these two cases in mind, as showing the different effects of digitalis under different circumstances.

ORIGINAL ARTICLES.

TYPHLITIS, PERITYPHLITIS, AND ALLIED AFFECTIONS, WITH SPECIAL REFERENCE TO TREATMENT.

By W. T. DODGE, M.D.,
SURGEON TO MERCY HOSPITAL, BIG RAPIDS, MICHIGAN.

TYPHLITIS is defined as "an inflammation of the cæcal region; perityphlitis as a morbid process commencing in the connective tissue surrounding the cæcum; and appendicitis as an inflammation of the vermiform appendix."[1]

Numerous differential diagnostic signs are pointed out by authorities, the most practical being those described as follows by Fitz:[2]

"The occurrence of three important symptoms, localized pain, fever, and circumscribed swelling in well-defined order indicate appendicitis. Prolonged constipation, late-appearing fever, pain of long duration, and doughy character of the tumor occupying the lumbar region indicate fæcal cæcitis. Constipation, early tympanites, retention of flatus, fever appearing late are symptoms of intestinal obstruction."

In practice the most expert diagnostician will often find it impossible to make a differential diagnosis. As will be seen in the cases reported in this paper, all the varieties of disease of the cæcal region are represented by a very similar array of symptoms, the more acute symptoms occurring in the case of perforating appendicitis with subsequent general peritonitis: and this is the point of most value to the attending physician. When the symptoms are acute and violent, and are not speedily relieved by a movement of the bowels, no time should be wasted, but an abdominal section should be immediately performed.

The cause of inflammation in the cæcal region is usually an accumulation of hardened fæces in the cæcum or ascending colon, or the entrance of some foreign body into the appendix.

The majority of cases that result in suppuration have their origin in the appendix. The attack is usually preceded by constipation and may come on with a chill.

There are always pain in the abdomen, referred particularly to the cæcal region, tympanites, general abdominal tenderness, but more marked in the right side, dulness on percussion over the right iliac region and sooner or later the development of a distinct tumor which can generally be recognized earlier by rectal examination than through the abdominal wall.

The important practical question that confronts the practitioner when he sees one of these cases is, in my opinion, whether pus has formed, or whether the symptoms are entirely due to the presence of hardened fæcal masses in the large intestine, which condition I believe to be usually the first stage of cæcal abscess.

In many instances, cases that present most grave symptoms, with every appearance of pus-formation, will rapidly recover when free fæcal evacuations have been obtained. In all cases in which the indications for immediate operative interference are not imperative, an attempt should be made to open the bowels at once, and I have found nothing so effectual for this purpose as the administration of full doses of sulphate of magnesium. I am in the habit of placing such cases upon tablespoonful doses of this salt given every three hours until fæcal evacuations are obtained unless the exhibition should be followed by increased pain. It is, also, a good plan to give large enemata of warm water.

Most writers are opposed to giving purgatives when symptoms of acute inflammation are present, but I have never seen ill effects from them, and have on several occasions been deprived of an opportunity to operate by the administration of a few doses of Epsom salts.

The patient should be relieved from excessive pain by the administration of opiates, soothing poultices should be placed upon the abdomen, and the diet restricted to liquids.

When free fæcal evacuations are not followed by improvement in the symptoms, or when it is found impossible to open the bowels, lateral abdominal

[1] Tiffany, in Reference Handbook of the Medical Sciences.
[2] American Journal of the Medical Sciences, October, 1886.

section should be performed without delay. If general peritonitis has developed, median section may be done, but under other circumstances the incision should be over the prominence of the tumor. A free incision should be made and the parts thoroughly examined. After opening the peritoneum, if doubt is entertained concerning the location of the abscess, a hypodermic needle may be inserted, and when pus is found the patient should be turned on his side, an incision made, a drainage-tube inserted, and the cavity thoroughly irrigated with boiled water. The walls of the abscess should be stitched to the parietal peritoneum, after which the abdominal wound should be closed around the tube.

The pus may be so thick that it will not pass through a hypodermic needle, and for that reason I am opposed to exploration before opening the abdomen.

The seat of the abscess should be carefully examined and if the inflammation originated in the appendix the latter should be ligatured and cut off. If rupture of any portion of the intestine is discovered, close it by means of Lembert sutures.

In some cases in which rupture into the peritoneal cavity has occurred it may be necessary to make median and lateral openings through the abdominal walls in order to break up the pockets and wash out all the pus. When the peritoneum has not been contaminated the cavity should not be washed out. The after-treatment consists in daily irrigations of the abscess-cavity, concentrated liquid nourishment, and general supporting measures. I append the histories of a few cases which well illustrate these procedures:

CASE I. *Perforating appendicitis; general peritonitis; death.*[1]—Male, aged twenty-five years. On September 26, 1882, while working in the field, he was taken with pain in the abdomen. I saw him on September 29th, and found that he had taken a purgative, which had produced free passages from the bowels but had not relieved his symptoms. He had but little fever, and at no time during his illness was the temperature higher than 102°. It was normal most of the time, particularly toward the end of the case, when general suppurative peritonitis existed. There was much tenderness in the right inguinal region, which soon extended over the entire abdomen.

On October 2d, after consultation, exploration was made with a hypodermic needle and pus obtained. An opening about two inches long was made through the skin, parallel with Poupart's ligament. The deeper tissues were divided on a director until the neighborhood of the peritoneum was reached, when the needle was again introduced and pus obtained. A small opening at the side of the needle was then made with a knife. A small amount of foul-smelling pus escaped. A drainage-tube was inserted and irrigation practised, but no improvement occurred and death resulted on October 7th.

Autopsy: Permission to hold a partial autopsy was obtained. General peritonitis was found, the abdomen being full of pus. A mass of hardened fæces occupied a rupture in the inflamed appendix.

This case occurred in the early days of my professional career, when I entertained more dread than at present of opening the abdomen. I should have made a larger incision through the peritoneum, washed out the cavity thoroughly, and ascertained the condition of the parts by direct examination. Then the ruptured appendix should have been removed and the abdominal cavity thoroughly cleansed. As no surgeon had, at that time, removed a ruptured appendix, and abdominal surgery is a development of later years, it is not surprising that I erred on the side of caution and conservatism. Such a half-hearted, timid operation would be inexcusable under similar circumstances at the present day.

CASE II. *Intestinal obstruction; symptoms simulating appendicitis; large doses of sulphate of magnesium; recovery.*—Male, aged twenty years. I was called to see the patient June 30, 1889, in consultation with Dr. Drummond, of Marlette, Mich., who had been attending him for three days. He had high fever, pain, and tympanites, with a localized tumor in the cæcal region. Dr. Drummond had given large doses of various purgatives and several enemata without procuring a passage of fæcal matter. I personally superintended the administration of a large enema, raising the hips and injecting a gallon of warm water, which, however, returned only slightly discolored.

I then recommended an immediate abdominal section, as the patient was in great pain; but his family being away, consent could not be obtained. While waiting for the arrival of his friends, I recommended the administration of a tablespoonful of sulphate of magnesium every three hours. This was given, and Dr. Drummond afterward told me that he gave in addition a dose of croton oil during the night, and repeated the enemata, with the result of procuring free fæcal evacuation at three o'clock in the morning. Recovery was rapid, and the patient was dismissed, cured, on July 15th.

CASE III. *Intestinal obstruction; probable pus-formation rupturing into the bowels; sulphate of magnesium; recovery, complicated by suppurating parotitis.*—Male, aged twenty-two years. I was called to see the case on March 28, 1890. He had been sick for two weeks, under the care of another practitioner, whom I was invited to meet in consultation; but as the gentleman did not appear, I was obliged to assume charge of the case.

The patient was taken with chills and pain in the abdomen, more severe in the right iliac region; was constipated throughout his illness, and was treated with enemata, and full and frequent doses

[1] Reported in detail in The Physician and Surgeon, vol. iv. p. 483.

of morphine and quinine. I found him free from pain, but under the influence of the morphine. The abdomen was distended and a well-defined, tender tumor occupied the cæcal region. The injections which had been given brought away small quantities of fæcal matter. His temperature was 102½° and his pulse 100. I was several miles in the country, in the midst of a violent snowstorm, and without instruments or assistance, or I should certainly have recommended an immediate operation, as I felt certain of the presence of pus. Under the circumstances I concluded to try the effect of salines, and to prepare for an operation on the following day. I directed the administration of a tablespoonful of sulphate of magnesium every three hours until some effect should be produced, and informed the family that probably an operation would be necessary.

At their request, Dr. H. M. Leach, of Saginaw, was invited to be present the next morning. At 9 o'clock in the evening I was again telephoned for, and was informed that the patient seemed much worse; but before my arrival a free evacuation from the bowels occurred and the aspects of the case had greatly changed. Six doses of Epsom salt were given before a movement was obtained. During the night several free evacuations occurred, and when Dr. Leach arrived in the morning the tumor and the serious symptoms had entirely disappeared, excepting the tenderness over the cæcum. The patient's progress to health was interfered with a few days later by the development of an abscess in the parotid gland.

The possibility of an abscess discharging by the bowel was considered, but the great quantity of fæcal matter precluded the possibility of finding pus, if it were present. The young man's mother was certain that she saw pus in his fæces a few days subsequently, which the occurrence of suppuration in the parotid would confirm. Restoration to complete health was slow.

CASE IV. *Recurring appendicitis; expectant treatment; recovery.*—Male, aged about thirty years. I saw him on July 25, 1890, in consultation with Dr. Atkinson, of Marlette. The man gave an interesting history. Several years ago he suffered from an attack of peritonitis, which subsided under treatment, but left a tender spot in the cæcal region which had persisted for several years, preventing the patient from participating in out-of-door sports and from doing manual labor; even riding in a wagon produced pain in the right side. He also stated that for some time he had noticed a tumor in the cæcal region, but that it gradually disappeared. He had suffered from chronic constipation for some years, but had been cured by his attending physician, Dr. Atkinson. On several occasions there had been recurrences of the swelling and pain in the cæcal region, confining him to his bed for some time, and then gradually disappearing without special treatment.

The present attack commenced a week previously to my visit, and was attended with considerable pain, especially upon attempting to exercise. His temperature had been more than two degrees above normal, and opiates were occasionally required at night to procure rest.

A well-defined, hard tumor, the size of a hen's egg, occupied the cæcal region, and was quite tender to the touch and movable. Our diagnosis was recurrent appendicitis, and the nature of the trouble was explained to the patient, together with the possible dangers and the probable result of an operation, as well as the possibility of acute symptoms supervening and necessitating an operation to save life. He chose the expectant plan of treatment. The tumor gradually disappeared, and the patient was doing his work (that of a bookkeeper) in three weeks.

Judging from the previous history, it is quite probable that this patient will have subsequent attacks, with possibly more serious results.

In my opinion, the performance of an aseptic abdominal section for the removal of the appendix, would be a wise and justifiable procedure in well-defined cases of this nature.

CASE V. *Constipation; abscess; abdominal section; recovery.*—Male, aged about twenty-five years. On August 8, 1890, I was requested by Dr. McCrae, of Marlette, to operate on this patient, whom he had seen on August 4th, in consultation with Dr. Wallace, of Elmer City. The patient had been ill for two weeks, and five years previously had what he said was an attack of peritonitis.

The present attack was preceded by constipation and was ushered in by a severe chill. Great abdominal pain, referred principally to the cæcal region, had been a prominent feature of his illness. His physician, Dr. Wallace, procured a movement of the bowels early in the case, and gave him excellent medicinal treatment. Dr. McCrae recommended an operation when he first saw the patient, but the friends did not give their consent. We now found him in considerable pain, with a tympanitic abdomen, and a well-defined tumor in the right side, most prominent in the cæcal region. His temperature was 102½°.

The friends hesitated to consent to an operation, although we pointed out its absolute necessity, and it was not until late in the day that they finally gave us permission to proceed.

Dr. Wallace anæsthetized the patient and Dr. McCrae gave me very valuable assistance during the operation.

I opened the abdomen in the usual manner, making a free incision over the prominence of the tumor. When the peritoneum was opened the cæcum and appendix appeared to be in a perfectly healthy condition. I was naturally much astonished at this, as we had diagnosed cæcal abscess.

A tumor could be felt under the cæcum, extending upward beneath the ascending colon. After passing a large aspirating needle into this mass several times a few drops of pus were obtained. The patient was now turned upon his side, aseptic cloths were packed around the intestines to keep them in place, and a free incision was made into

the abscess. More than a quart of thick, fæcal-smelling pus escaped.

I passed my finger into the cavity and found that it extended half-way across the abdomen, and was separated from the peritoneal cavity by only a thin membrane. There was rather free hæmorrhage from the sac, but it was controlled by injecting hot water.

The cavity was thoroughly washed out with boiled water, a drainage-tube was inserted, and the abdominal wound united with catgut, care being taken to attach the parietal peritoneum to that covering the abscess-wall.

Darkness came on soon after we commenced, and the greater portion of the operation was done by lamplight. Free discharge continued for several days, but gradually subsided. The abdominal wound, excepting where the drainage-tube was inserted, healed by first intention.

The after-treatment was conducted by Dr. Wallace, and consisted of daily irrigation, at first with boiled water, subsequently with astringent solutions.

The patient's general condition improved rapidly, and there was no elevation of temperature until three weeks after the operation, when he arose and walked into an adjoining room, and was immediately taken with violent pain, followed by an elevation of temperature to 102°.

This trouble gradually subsided, and Dr. Wallace wrote me on October 18th that the patient was then sitting up from two to fours daily, and was gradually gaining strength.

ROUGE'S OPERATION FOR THE REMOVAL OF A NASAL SEQUESTRUM.[1]

BY CHARLES H. KNIGHT, M.D.,
OF NEW YORK.

IN the opinion of Rouge,[2] of Lausanne, whose name has been given to the operation presently to be described, the condition known as ozæna is invariably associated with some lesion of the bony framework of the nose. Proceeding on this theory he tried to devise a method of operating on these unfortunate cases which should give more room for exploration and at the same time be devoid of excessive risk. He found that the dimensions of the entrance to the nasal fossæ might be considerably increased by separating the soft parts from the upper jaw, thus permitting the nose to be tilted upward toward the forehead. This procedure answered admirably in the case the history of which follows:

H. H., mulatto, aged thirty-five years, single, a waiter, came under my observation in December, 1879, having had, six weeks previously, a genital chancre. He had received only local treatment, although about three weeks after the chancre appeared he had a rash on his trunk and arms, and a sore throat. At the time of his visit to me the eruption had faded, but the chancre had not yet healed, and his tongue and tonsils were covered with mucous patches. He had enlarged inguinal, post-cervical, and epitrochlear glands. He suffered somewhat from osteocopic pain, and there was some alopecia. The general condition of the patient was good, and he was a man of good habits.

He was put upon mercurial treatment, under which he continued for about six months. In November, 1880, one year after infection, patches of tubercles appeared on his forehead and in front of his left ear. The tubercles ulcerated and coalesced, forming an open sore, which was very persistent, but finally yielded to mixed treatment and the local use of acid nitrate of mercury.

He had no more trouble until two years ago, when a swelling appeared in the roof of his mouth and his nose became so obstructed that at times nasal breathing was impossible. The swelling over the hard palate softened and ruptured, and at the same time several small pieces of dead bone were expelled from the nostrils.

He did not again come under my care until two months ago. At that time the septum had been completely destroyed but the columna was intact. The turbinated bones were gone, there were a large, partially-detached sequestrum lying on the floor of the nose, and a perforation of the hard palate far forward. The central incisor teeth of the upper jaw, and the alveolar process and the bone of the maxilla itself at that point were missing. The patient's sense of smell was abolished, but the odor emitted from his nose was almost intolerable. There was remarkably little external deformity, the change of contour being limited to a very slight depression just below the bridge of the nose.

My efforts were first directed to removing the sequestrum piecemeal by the use of cutting-forceps and the electric drill. The patient proved to be so intractable, in spite of the free use of cocaine, that nothing could be accomplished, and I determined to remove the bone at one operation, with the aid of anæsthesia. This was done at the Manhattan Eye and Ear Hospital, September 16, 1890. The patient was etherized and placed on his back with his head dependent. An incision was made along the gingivo-labial fold of the upper jaw, and the alæ of the nose were dissected from the subjacent bone. The lip and the tip of the nose were everted and forcibly retracted upward, exposing the nasal cavity. The sequestrum was then seized with forceps and found to be firmly attached posteriorly. With the aid of my forefinger passed through the hole in the hard palate, and by a twisting process it was finally disengaged and was dragged forward; but it could not be withdrawn until the fibrous band which completed the arch of the maxilla was divided. Even then considerable force was required, and the lateral incisor teeth were so loosened that they had to be removed. Hæmorrhage was free, but by no means alarming. The parts were replaced, no dressing whatever being used. The

[1] Read at a meeting of the Laryngological Section of the New York Academy of Medicine, October 28, 1890.

[2] Nouv. Méthode pour le Trait. chir. de l'Ozène. Lausanne, 1873: Bull. Soc. Méd. de la Suisse Rom., Lausanne, 1868, vol. ii. pp. 265–68; Cong. period. internat. des. Sci. Méd., Compte rend., Genéve, 1878, pp. 337–54. San Francisco Western Lancet, 1880–81, vol. ix. pp. 200–4. Translated by Whittelly.

patient was kept in bed, put upon fluid diet, and not allowed to talk. The mouth and nasal cavity were frequently irrigated with a weak carbolized solution.

On the second day he left the hospital, having had no unfavorable symptoms. A week later two fragments of bone were removed through the nostrils, the wound in the mouth having healed.

The present condition of the patient is one of relative comfort. Fœtor is almost entirely absent, but there is and always will be more or less annoyance from the accumulation of secretion in the nasal cavity. The discomfort in eating and speaking, due to the perforation of the hard palate, may sometime be overcome by the adjustment of a dental plate. Meanwhile the opening has to be kept plugged with absorbent cotton.

It is difficult to determine what this sequestrum represents, both on account of its peculiar shape, and because the destruction of the bony walls of the nasal fossæ was so extensive. It is apparently the palatal process of the right superior maxilla, or the horizontal plate of the palate bone much thickened by inflammatory deposits. The normal landmarks have disappeared. The interior of the nose is converted into one immense cavity, its left wall being quite smooth, its floor being deficient anteriorly, and on the right side freely communicating with the cavity of the maxillary sinus.

In connection with the specific history given by this patient, it should be added that the man was married three years ago. His wife has never conceived, and has not given the slightest evidence of syphilitic infection. The patient himself has had no recent symptoms of active syphilis. The extraordinary destruction caused by the disease was, in my opinion, largely due to his neglect of treatment. Whether the concentration of its effects upon the nose was invited by some preëxisting intranasal lesion or deformity, I am unable to say.

In a discussion on deflection of the nasal septum, at the recent meeting of the British Medical Association, Woakes[1] expressed the opinion that Rouge's operation affords but little additional room, and my limited experience leads me in a measure to share this view. But for the loss of the median portion of the superior maxilla and division of the connecting fibrous band, this large sequestrum, which measured one and one-half inches in length and one and one-eighth inches in width, could not have been removed unbroken.

Although septal deflections are perhaps the most troublesome and perplexing condition with which we have to deal, yet the part usually involved is so accessible through the nostrils that the methods in ordinary use should suffice, provided the resiliency of the cartilage be destroyed. The obstacle to success lies, not so much in the contracted space in which we have to operate, as in the difficulty of overcoming the spring of the cartilage.

[1] British Medical Journal, September 13, 1890.

A recent number of the *Lancet*[1] contains an elaborate account of a case of deviated septum occurring in a boy seven years old, for which Rouge's operation was done by Mr. Clinton Dent. The operator suggests that the severity of the operation may seem disproportionate to the condition to be rectified, but consider it justified by the disfigurement which may be present in the case, by extreme impediment to breathing, and by the probability of serious complications should lung trouble supervene. The reasons enumerated are certainly excellent ones for attempting to remedy the condition in some manner, but they hardly seem to authorize the selection of a comparatively intricate method, provided the results are attainable in a simpler way.

Rouge's interest in the new operation, and, one might add, his misconception of the pathology of ozæna, may have led to the unnecessary use of his method; nevertheless it must be admitted that most of his results have been remarkably satisfactory. With one exception, in every case the symptoms were promptly and completely relieved. One of his cases, that of a woman[2] twenty-eight years of age, who died of pyæmic meningitis on the sixth day after operation, very forcibly illustrates the necessity of extreme caution in manipulating the upper part of the nasal chambers. In this case the whole of the perpendicular plate of the ethmoid was removed, and the os panum was gouged away over an area of about one centimetre, so that the finger could be passed directly into the right orbital cavity. At the autopsy the ethmoid bone was found to be healthy and uninjured and the cribriform plate was intact. There were no purulent foci in its vicinity, but the ophthalmic vein was occluded by a purulent clot and there was general suppurative meningitis. Such an accident might of course follow any operation, especially if encouraged by neglect of antiseptic precautions or by the use of excessive violence. In studying the human skull one cannot avoid being impressed by the extreme delicacy of the osseous tissue forming the roof of the nasal cavities, and by the fact that the effects of traumatism inflicted in this region might readily be transmitted to the cerebral fossa. Operative interference in this neighborhood should therefore be conducted with the utmost care. The fatal result in this case should certainly not be considered an argument against Rouge's operation. An equal degree of injury might easily have been done by an operation performed through the anterior nares.

Opinions differ as to the merits of Rouge's operation. Lucas[3] considers it free from danger, and in

[1] July 28, 1890, p. 1425.
[2] Watson: Diseases of the Nose and its Accessory Cavities.
[3] Lancet, January 20, 1883.

many cases advantageous. Harrison Cripps[1] thinks it easy of performance, and narrates a case in which he met with no annoyance whatever from hæmorrhage. Haward[2] has a high opinion of the method, and gives histories of four cases in which he resorted to it without accident. D'Azambrya[3] recommends it only for intractable cases, recognizing the possibility of phlebitis and purulent infection.

According to Beverley Robinson,[4] Trélat thinks that it should not be done, on account of hæmorrhage, the difficulty of performing it, and because of its inefficacy, he having had no successful result. Robinson himself seems to regard the danger of hæmorrhage as an important objection, which is hardly counterbalanced by any decided gain in space offered by this method. On the other hand, Bosworth[5] makes light of the risk and the difficulty of the operation. He thinks it interesting from an historical point of view, and from its novelty, and remarks that in many cases it best meets the indications.

In a recent paper by W. Spencer Watson, entitled "Ozæna and Some Other Forms of Rhinitis," may be found the following description of a so-called *failure* of Rouge's operation:[6]

"A girl, aged seventeen years, was under my care at the Great Northern Hospital with very obstinate ozæna. The results of treatment were so far unsatisfactory that the patient went to another hospital and placed herself under the care of a distinguished surgeon, who performed Rouge's operation for her. She afterward again presented herself at the Great Northern, and considered herself cured. There was, however, distinct evidence of the ozæna stench in her breath. I afterward met the surgeon who operated on her, and he very frankly acknowledged that though he had expected to reach some carious or necrosed bone, none had been found, and that he had been disappointed in the results of the operation. He also expressed his opinion that it was not so easy a proceeding as he had anticipated, and that there had been rather embarrassing hæmorrhage."

I would venture to criticise the title of the paper, as well as the opinion which does not discriminate between failure of an operation and lack of judgment on the part of an operator. Ozæna is not a form of rhinitis: it is a *symptom* of a form of rhinitis. Rouge's operation should never be undertaken until we know for what purpose it is to be done. The class of cases to which it seems to be particularly adapted is that of which my own is a typical example, namely, syphilitic necrosis of the skeleton of the nose. In this condition the sequestra are apt to be of large size and irregular shape, hence their withdrawal through the natural passages involves unnecessary pain to the patient and unwarrantable damage to the soft parts. The importance of their early removal must be admitted for several reasons. The prolonged retention of necrosed bone must impair the general health, and is at the same time a constant menace to adjacent healthy structures. Moreover, it renders the patient a burden to himself and to his associates.

The chief advantage of this method of operating is that an external wound is avoided, a point of no little importance with some individuals. There is no doubt that it does give some additional space, which may be still further increased, if necessary, by removing a part of the bony wall of the nasal fossæ. Even the slightly-increased space may be just enough to permit the extraction of a jagged piece of dead bone, the removal of which would otherwise have caused considerable laceration.

Finally, although apparently a formidable operation, it is not, in reality, especially hazardous. Hæmorrhage may be copious, but should be readily controlled by pressure, and the process of repair is rapidly completed without deformity.

REPORT OF A CASE OF SARCOMA OF THE OMENTUM AND LIVER.

BY J. M. ANDERS, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND HYGIENE IN THE MEDICO-CHIRURGICAL COLLEGE; PHYSICIAN TO THE EPISCOPAL AND PHILADELPHIA HOSPITALS.

THE following case of sarcoma, which came under the observation of the writer during his last term of service at the Philadelphia Hospital, is reported on account of the immense size of the newgrowth, and, more especially, because of the great rarity of sarcomata in the location in which this was found:

C. B., aged thirty-five years, white, a native of Switzerland, and by occupation a laborer.

Family history: No family history of tumor; his mother died of dropsy; his father is living, sixty-two years old, and in good health.

Previous history: The patient had scarlet fever in childhood, and one attack of gonorrhœa; has had three healthy children. His wife miscarried once.

History of present illness: In May, 1889, the patient first noticed a small tumor low down in his abdomen, but gave it little thought. The tumor increased in size, and he had some indefinite abdominal pains—never cutting or severe—with slight diarrhœa and headache. Later, he complained of frequent micturition, and of severe abdominal distress when his bowels became constipated. In the early part of October, 1889, he passed portions of a tapeworm; and on October 9th was placed on anthelmintic treatment, which resulted in the passage of a long portion of the body of the worm. The patient was so much weakened by this treatment that he was not subjected to it again.

Meanwhile the abdominal mass continued growing. It was hard, distinctly nodulated, and slightly

movable. There was neither pain nor tenderness. The lower portion could be followed backward above the pubes, as though extending down into the pelvis. The entire growth could be distinctly outlined. On rectal examination, a mass was found in the pelvis and, seemingly, extending to the abdominal cavity. Soon after the patient entered the hospital the liver was found to be normal in shape and size—the edge was not felt—and so remained until a few weeks before the patient's death, when it began to extend below the ribs, and at last was easily felt as a large mass in the epigastric and right hypochondriac regions. Examination of the urine was negative; neither albumin, sugar, nor casts were found.

Thus the case continued; the patient did not emaciate, and his general health was fair; he frequently required purgatives, and was more or less comfortable after evacuation of his bowels. During the last week of life he lost flesh very rapidly, and died quite suddenly, apparently in great pain, after a few hours' unconsciousness.

Autopsy: Body that of a fairly well preserved white man. Abdomen tender and distended. Blue discoloration of the skin over the abdomen. At once, on opening the abdominal cavity, a large, whitish-pink, markedly lobulated and furrowed mass was exposed. The larger part of this extended from the pubes (with a small prolongation extending to the brim of the pelvis) to the ensiform cartilage. There was an adhesion to the abdominal wall just above the pubes. Above, the entire mass was seen to depend from the great omentum, at the root of which was attached a smaller mass. These two portions involved the omentum alone, and were not connected with any of the neighboring structures, excepting by a few inflammatory adhesions. Together they weighed thirteen pounds. On section, they were firm—about the consistency of a fibroid tumor—somewhat softened, and of a pinkish-white color. In the centre of the larger growth was a cavity the size of a large apple, containing a little whitish, watery fluid. A mass was then found attached to the peritoneal covering of the sigmoid flexure. This presented the same structure and appearance as the others, and was of the size of a large fist. A third mass was found filling the cavity of the pelvis and attached to the rectum and partly to the bladder. This was contiguous to the abdominal growth, but not at all connected with it. A fourth mass was attached to the ascending mesocolon, and by inflammatory adhesion to the abdominal wall.

The liver was removed, and was found slightly adherent to the diaphragm. Everywhere projecting from the surface were small and large nodes. In removing the organ a small node was detached from its position and left a round cavity lined with a smooth wall. On section, the nodes were found to be exactly similar to the large abdominal growths. The liver weighed more than eleven pounds. The gall-bladder was stained a bright yellow, but otherwise was normal.

The spleen appeared normal in every respect.

The kidneys were markedly congested, but otherwise of healthy appearance.

In the intestinal canal there was discovered a tapeworm (tænia solium), which was removed entire. Its exact location was, unfortunately, not determined. The intestines, which were pushed up into the right hypochondriac region, were normal.

The heart was healthy.

The lungs were normal, except that the lower right lobe was compressed by the enlarged liver.

On microscopical examination, the growth seemed to be a round-celled sarcoma.

As may be seen from this report, no lesions were found other than those in the liver and peritoneum.

To the above notes, which have been so ably detailed by my resident physician, Dr. Stengel, nothing remains to be added save, perhaps, a brief reference to the temperature-record. The temperature-chart shows that during about one-half the time that the patient was in the hospital there was slight elevation of temperature with remissions which occurred more frequently in the mornings than in the evenings. During the remaining time, including the last eight days, the temperature was subnormal. There was nothing unusual about the pulse, which

FIG. 1.

Upper portion of cut is the anterior surface of the tumor. At the extreme left was the attachment to the omentum.

FIG. 2.

Growth inverted.

varied from 80 to 114 beats per minute. The number of respirations per minute varied from 22 to 32.

REMARKS.—Excluding carcinoma, primary neoplasms of the serous membranes are regarded by high authorities as rare and sarcoma as very rare.[1] Waldeyer[2] has described a case of plexiform angiosarcoma of the peritoneum. After considerable painstaking investigation, I have been unable to find any references to other recorded cases than that of Waldeyer, and this a mere allusion. The question may arise in the mind of the reader, Was the omental growth a primary or a secondary one? According to the history, a small hard tumor was first observed by the patient "low down in the abdomen." Again, on account of the enormous size of the omental tumor (see cuts), coupled with the history of the progress of the case from the date of admission to the date of the patient's death, it is quite certain, I think, that the omental growth was primary. At all events, evidences tending to show that the liver was implicated were wanting until late in the course of the disease. Again, the liver is prone to be the seat of metastatic growths on the one hand, and is extremely rarely the seat of primary sarcomata on the other.

The disease in this instance must have been rather rapidly disseminated, as shown by the several distinct masses, including metastasis to the liver, in this respect following a law of sarcomata, more particularly of the round-cell variety.

1637 N BROAD STREET, PHILADELPHIA.

THE TREATMENT OF ECTOPIC PREGNANCY.

BY J. M. BALDY, M.D.,
OF PHILADELPHIA.

OF the total number of cases of extra-uterine pregnancy there can be no doubt whatever that a certain number go on to a spontaneous cure, and I believe that many more terminate in this manner than we at present imagine. The most common method is by a rupture into the folds of the broad ligament, the death of the embryo, and a gradual complete or partial absorption of the resulting hæmatocele, embryo, and membranes. That death of the embryo may occur before rupture, and while it yet remains in the tube, is, I think, not only possible, but probable in a certain proportion of cases. The result in such a case would be the same as in the former. Just what proportion of cases end in this happy manner is a mere matter of speculation.

These results would naturally make us take into consideration, as one of the methods of treatment, theoretically at least, the expectant plan; but I know of no authority bold enough to advocate it practically. Such a large number of cases terminate fatally, and the dangers to the patient are so great that, at the present time, it is thought necessary to take some active steps in treating every case which comes under observation, and not to take any chances of disaster overtaking the patient. This course seems to me to be the only reasonable one, and when a case is even only suspicious, active measures should be taken to prevent the possibility of future trouble.

In considering the treatment of extra-uterine pregnancy I shall confine myself to the period before rupture. All are agreed that after rupture of an ectopic gestation-cyst has taken place there is but one proper treatment, viz., abdominal section. In the discussion of the relative merits of abdominal section and electricity it has too often been assumed by the opponents of the electrical treatment that this treatment is recommended for the post-rupture period. This is not true; no one whose word carries the slightest weight recommends the use of electricity after a rupture has taken place into the abdominal cavity, or after a rupture into the folds of the broad ligament, beyond a certain period, the limit being generally fixed at or under four months; later than this, even electricians recommend either waiting for a viable child and then laparotomy, or laparotomy at once.

There are but two forms of treatment which I shall consider, viz., abdominal section and electricity. All operative procedures from the vagina, except in very exceptional cases, are unscientific and bungling; the sac cannot be removed without the greatest difficulty (if it can be removed at all), and the removal of the whole sac is a great desideratum. Puncture methods, with the object of drawing off the liquor amnii and killing the fœtus, have, in times past, proven so disastrous that I do not think that, with our present safe methods of dealing with the disease, anyone would knowingly attempt them; certainly no one in America. The injection of morphine into the sac, as practised by Winckel and others in Germany, has not proven a success, even in their hands. In Winckel's *Text-book of Midwifery*, translated by Edgar, eleven cases are mentioned as having been treated in this manner. Of the eleven, three were fatal, a mortality of almost twenty-five per cent. The merest tyro could not reproduce such an unfortunate record with either electricity or surgery.

The only method of applying electricity which will be included in my subsequent remarks is the passage of either a faradic or galvanic current through the gestation-sac without a puncture being made. Certain writers, especially foreigners, have

[1] It is well to bear in mind that tumors of the subserous tissues are common, including sarcoma.

[2] A Text-book of Pathological Anatomy and Pathogenesis, by Ernst Zeigler, p. 137.

persistently and, it would almost appear, wilfully misunderstood Americans when they talk of the use of electricity in this disease. The advocates of this method of treatment have always and most emphatically claimed that they did not puncture, and that it was dangerous to do so. In the face of all that has been said on this subject, it is simply gross ignorance, or worse, to misunderstand longer and misquote. The contention, then, is between abdominal section and electricity applied after the most approved methods. I make no distinction between the faradic and galvanic currents. Both are used, both are recommended with equal fervor, and apparently are followed by about the same results.

The advantages of the treatment of extra-uterine pregnancy in the prerupture stages by laparotomy may be summed up as follows:

1. By the operation the fœtus, membranes, and sac are completely removed.
2. Any complicating disease which may exist can be successfully dealt with at the same time.
3. All immediate danger from the existence of the abnormal gestation is at once and forever removed.
4. All possible future trouble from the occluded tube is removed.
5. In cases of mistaken diagnosis, whatever may be found will require surgical intervention, and therefore the mistake is productive only of good.
6. The operation has very little, if any, mortality, and is safe in the hands of anyone who can do a laparotomy with safety.

The disadvantages claimed for the operation by its opponents are:

1. The dangers of the operation itself.
2. Unsexing and mutilation of the patient.
3. The possibility of mistakes in diagnosis, and the consequent unnecessary operation.
4. The patient's horror of an operation.

The advantages of the electrical treatment, as claimed by its advocates, are:

1. The certainty of killing the fœtus.
2. The probability of the absorption of the sac-contents, and the subsequent shrinkage of the tube to a natural size.
3. When the sac-contents are not absorbed, the harmlessness of the remaining tumor.
4. The possible future impregnation of the patient.
5. The avoidance for the patient and friends of the horrors of an operation.
6. The harmlessness of the treatment if a mistake in diagnosis be made.

The disadvantages claimed for the electrical treatment by its opponents are:

1. The uncertainty of killing the fœtus.
2. The danger of delay necessarily incident to the treatment.
3. The dangers during the treatment.
4. The harm done in case of mistaken diagnosis.
5. The dangers to the patient after the treatment is finished.
6. The doubtful nature of the disease in many of the cases treated in this manner.

First, as to the treatment by abdominal section. The points of advantage, as claimed by its advocates, and as given above, make it an ideal treatment in its results, provided those claims can be substantiated. Several of these claims are questioned by its opponents, and we will consider them *seriatim*.

1. It is claimed that laparotomy is a dangerous operation at all times and under all circumstances. This must theoretically be granted at once, but when practically applied to extra-uterine pregnancy it cannot be shown to have existed in the past few years, unless it be in the hands of incompetent men. I am unable to find in the literature of the subject a single case of death following the operation when performed in the pre-rupture stages; and even after rupture there are no deaths which can be justly attributed to the operation—in almost every instance of death the patient was beyond help in consequence of hæmorrhage or shock, or both. On the other hand, look at the long list of brilliant results as reported in the New York and Philadelphia Obstetrical Societies, to say nothing of Tait's individual list of forty-two cases. In the face of this overwhelming evidence, in order to substantiate the fact of danger, a list of bad results must be produced; and as yet no one has had the temerity to attempt this

2. The unsexing and mutilation of the patient.

In no other part of the body is it considered mutilation to remove a useless, diseased, and dangerous member. This cry is merely the plea of the demagogue, and savors of a species of political trickery unworthy of a respectable scientist. The patient is not mutilated, and it is rank nonsense to say that she is. She certainly is unsexed, in the sense that she cannot become again impregnated upon the side from which the sac was removed; that she is unsexed in any other sense is untrue. It must be remembered that almost always the disease is unilateral, and the opposite side remains undisturbed, and in good condition for performing its functions. The case of Tait's[1] which became impregnated a second time after the removal of a unilateral ectopic gestation proves the truth of this. But it is said that double tubal pregnancy exists at times! This is true, and in that case the sterility would be complete. ' It has never been proven in a

[1] Diseases of Women and Abdominal Surgery, 1889.

single case that the woman is not just as sterile after a cure by electricity, or even after a spontaneous cure, as she is after the operation. A case or two may have become pregnant after such treatment, but how can it be proven that the impregnation did not take place on the opposite side, as was the case in Tait's patient, as well as in several others on whom the operation was performed? Both theoretically and practically all the facts are against the electricians, and they must either prove their point or abandon it.

3. The possibility of a mistaken diagnosis, and the consequent unnecessary operation.

In competent hands, even though a mistake in diagnosis be made, the operation will not have been unnecessary. No pelvic tumor exists, which gives rise to symptoms sufficiently serious to cause a diagnosis of ectopic gestation, and which does not require treatment, and the most generally accepted treatment for all these diseases is laparotomy and removal.

4. The horrors of the operation to the patient and her friends.

This is incident to all operations, great or small, and cannot be entirely avoided, however much it is to deplored. I have never found a great amount of trouble from this. When I have explained to the patient and her friends the supposed nature of her complaint and pointed out its dangers they have generally been anxious for the operation and did not display half as much anxiety over it as they did over the disease. Electricity itself is not altogether free from the same objection as far as the patient is concerned. To frighten a woman, it is merely necessary, as a rule, to tell her that something has to be done. Women are not much given to discriminating between degrees of danger in operations. An operation is usually much the same to patients, whether laparotomy, cutting off a toe or applying electricity to kill something, although it must be admitted, that, as a rule, they would object to electricity the least if the choice were given them.

It would seem, then, that the claims for the advantages of the surgical operation are well established, and that in the operation we have an ideal treatment. Here we could rest content did not the advocates of the electrical treatment claim equal advantages for their method. If these advantages as claimed and as given above can be substantiated, it must be admitted that it is equally ideal with the surgical procedure, and the patient must in each case be given her choice, after the advantages of each have been impartially placed before her. In such an event, that she would in the majority of cases choose the electrical treatment is pretty certain.

To these supposed advantages of electricity certain objections are made by its opponents, and, as in the case of the surgical treatment, we will consider these objections *seriatim*.

1. The uncertainty of killing the fœtus.

Coe[1] reports the case of a woman who was supposed to be suffering from extra-uterine pregnancy. Her doctor, who was a most careful practitioner, used first a strong galvanic and then a faradic current with the view to destroying the fœtus. As a result of the application the patient had severe uterine colic and more or less shock. After this treatment had continued for two weeks the patient had an attack of abdominal pain more severe than before. Dr. Coe saw her at this time. During the following week she was reported as growing worse and had become very feeble, and her physician feared that peritonitis was developing. Finally she had another attack of pain with apparent collapse, and an exploratory incision was made, only to find a normal pregnancy of three months. The patient recovered from the operation and aborted later. In this case not only was an extra-uterine pregnancy incorrectly supposed to be present, but the electricity failed to kill the fœtus.

Buckmaster[2] reports the case of a patient who had fibroid tumors of the uterus and who became normally pregnant. Not being aware of the pregnancy, at the third month of gestation he put the woman under chloroform and passed twenty milliampères of a galvanic current for twenty minutes; in spite of this the patient went to term and was delivered of a living child.

Bovee[3] reports the case of a patient who had formerly been a patient of Chadwick's, of Boston. Dr. Chadwick had diagnosed the case in the ninth week and applied electricity in the eleventh week, and, he thought, killed the fœtus. At the end of five months Bovee delivered a five months' fœtus from the vagina. It was pronounced a five months' fœtus by Billings and Lamb in Washington, and later by Minot in Boston, who believed that the pregnancy had advanced to one hundred and fifty-three days, and could not reconcile this with the opinion that the fœtus was destroyed by electricity in the eleventh week.

Wylie[4] records a case in which electricity had been used under ether several times and yet the fœtus lived. It was finally killed by injections of morphine and as a result of this treatment the contents of the sac suppurated and the patient lost her life, an operation failing to save her.

I could give a number of other failures to kill the fœtus, but will mention only one more. The case has not yet been published, but full details will soon

[1] American Journal of Obstetrics, January, 1890, p. 95.

[3] Annals of Gynecology, July, 1890, p. 538.
[4] American Journal of Obstetrics, vol. xxiii. No. 2, 1890.

be given the profession. The woman was a patient of Dr. Morris J. Lewis, of Philadelphia. She was seen in consultation by Dr. B. C. Hirst and extra-uterine pregnancy diagnosed. Dr. G. Betton Massey was called in to apply electricity for the destruction of the fœtus. Six treatments were given, the galvanic and faradic currents being used on alternate days. Over one hundred milliampères of the galvanic current and the full force of the faradic current were given at each of the respective sittings. The three attendants then agreed that if the fœtus was not dead they could not kill it. The woman went on from bad to worse, and a month later Dr. C. B. Penrose removed a growing tubal pregnancy.

Further comment on this is unnecessary. It is simply folly to insist that electricity is sure death to the fœtus in the face of such evidence.

2. The dangers of delay necessarily incident to the treatment.

These are by no means small. Although a tubal pregnancy *may* continue to grow until the thirteenth week or later without rupturing, yet it only too often ruptures much earlier. I assisted Dr. Montgomery[1] in an operation on a patient to whom this accident happened in the fifth or sixth week. Electricity was being applied at this time.

Montgomery[2] records yet another case in which the rupture took place at the fifth week.

Engelmann[3] records a case of the disease in which rupture took place earlier than the fourth week, as proven by the size of the gestation-sac and the fact that no menstrual period had been missed.

Dr. R. P. Harris[4] says that he knows of two cases in which rupture occurred as early as the third or fourth week. Rupture may occur at any period, and no one can predict just when. For this reason, if a diagnosis is made, or if the disease is strongly suspected, it is not safe to adopt a treatment which avowedly must continue for a number of days, and probably for a week or two. A case in point is one which was taken by a New York physician to the office of Dr. T. Gaillard Thomas for an opinion. Dr. Thomas diagnosed extra-uterine pregnancy, and advised delay and the use of electricity. While in the street, on her way home from the doctor's office, the rupture took place, and the woman had a narrow escape from death. These cases and those seen by Dr. Formad, the coroner's physician of Philadelphia, show that rupture may take place at any time between an early and a late period. A close inspection of the literature of the subject will give the most sceptical plenty of material for thought.

3. The dangers during the treatment.

These dangers are strenuously denied by many.

Brothers[1] reports four cases in which alarming symptoms supervened during or immediately after the treatment, and there are many others in his list in which minor bad symptoms followed.

Coe[2] records a case of extra-uterine pregnancy at the second month, which he saw in consultation, in which the diagnosis was confirmed by the late Dr. Hunter. The faradic current was used, the sac ruptured, and it was easy to detect gradual increase of the resulting hæmotocele.

Janvrin[3] reports a case in which death followed the third application of electricity, on account of rupture of a vessel in the wall of the sac.

4. The harm done in case of a mistaken diagnosis.

It is contended that no harm can possibly be done in the event of a mistaken diagnosis. I have not had time to go over the records, and look up these cases, but will refer to one case reported by Dr. T. Hewson Bradford, and which I myself saw, in which electricity was given by Dr. G. Betton Massey through a pelvic mass, the diagnosis being incorrect. The case proved to be one of intra-ligamentary cyst. During two applications the woman became so alarmingly ill that the treatment was discontinued, and the knife resorted to by consent of all the physicians concerned in the case. I have during the past two years seen at least half a dozen patients go to bed and remain there for a week or more with an alarming attack of peritonitis after a single treatment in the hands of an expert. Everyone who has any experience with electricity must have seen similar cases, and know only too well that harm may result from sending a current of electricity promiscuously through pelvic growths.

5. The dangers to the patient after the treatment is finished.

Brothers[4] records two cases (Lusk and Chadwick) in which suppuration with discharge of the fœtus occurred in consequence of the use of electricity.

J. P. Tuttle[5] records a case in which, after the electrical treatment, he delivered a four-months' fœtus *per rectum*.

G. M. Tuttle[6] records a case of between two and three months, in which the faradic current was applied daily for ten days. He says: "In this case the thorough and intelligent use of electricity for the purpose of destroying the embryo was followed by no evident amelioration of symptoms, which, on the contrary, continued to grow worse with an uninterrupted increase in the size of the tumor." In this case, not only was the danger not abated,

but the electricity failed to kill the product of conception.

The claims made by the electricians that after the death of the fœtus all trouble is over, would seem to be disproved by these cases, amounting to about eight per cent. of the whole number of women treated, and supposed to be cases of ectopic gestation. In addition to these the literature is full of similar cases, in which the fœtus died from causes other than electricity. The after-results, however, of such cases can differ in no way from those killed by electricity. If the claims of the electricians are correct, then after the death of the fœtus, from whatever cause, the results must be the same, viz., absorption and shrinkage.

Thompson[1] records a case of extra-uterine pregnancy in which death of the fœtus occurred between the second and fourth months. Later, the fœtal bones were passed by the bladder.

Goelet[2] records a case suffering from supposed pelvic hæmatocele. A vaginal incision was made behind the uterus, and a fœtus of about the third month, in a state of decomposition, was removed.

Tuttle[3] records three cases in which the fœtus died early, and after varying periods of continued suffering the sac and contents had to be removed.

And so it is all through the literature—the number is legion. In addition to these cases, Hanks[4] reports that in a series he has collected, in four cases the fœtus sloughed into the rectum, in one into the bladder, and in four into the uterus.

Brothers[5] has tabulated fifty cases of supposed extra-uterine pregnancy treated by electricity, all he could collect from literature, and yet, strange to say, he has missed many with bad or indifferent results, some of which are included in this paper. Of these fifty cases fifteen are noted, after periods of from three months to three years, as still having pelvic masses, some of them the size of a goose-egg, a pigeon-egg, a man's fist, etc. Does anyone doubt that the time is coming when some of these very women will have a repetition of their troubles, and will require an operation for relief? Is this the kind of cure the electricians boast of?

6. The doubtful nature of the disease in many of the cases reported as treated in this manner.

In connection with this, does not the fact that out of the grand total of fifty, fifteen cases still have masses of considerable size in their pelves, form presumptive evidence that some of the cases had something besides ectopic gestation? If the difficulties of diagnosis have not been overcome by the surgical men (as I have proven by many cases reported elsewhere),[1] is it strange that the electricians should make as large a proportion of mistakes in the same direction? The same gentlemen who have verified the diagnosis in many of the electrical cases, and on whose opinion the truth of the diagnosis is based, have been proven to be mistaken in other cases in which they made just as positive diagnoses, and have themselves repeatedly said that they have over and over made the mistake. By what reasoning can it be claimed that they are infallible in just the cases in which it is impossible to verify the diagnosis?

Nor is this presumptive evidence all that there is against the electricians on this point. Wylie[2] has proven by post-mortem examination that three supposed cases of ectopic gestation, treated by electricity, were not such at all.

In three more (McBurney, Garrigues, and Trask) the fœtus was discharged by the natural passage. Almost to a certainty these were cases of normal gestation. It is not at all strange that such a mistake in diagnosis was made; there are many cases on record in which a normal pregnancy was overlooked, even after the sound was repeatedly passed. The case of Coe, quoted above, in which electricity failed to relieve, and an exploratory laparotomy revealed a normal pregnancy, is a case in point. Had the exploration not been made, that case would have been on record to-day as a case of interstitial pregnancy in which the electrical treatment forced the fœtus into the uterus; and with exactly as much ground for the supposition as the three cases of McBurney, Garrigues, and Trask.

I cannot review each of the reported cases in detail, but shall refer to a few, and show how doubtful was the diagnosis even as reported. But, first, let me call attention to the cases of Cushier and Harrison, in each of which the credit for the cure has been given to electricity, to which it does not belong.

T. Gaillard Thomas[3] saw the case of Cushier in consultation, and a diagnosis of ruptured interstitial pregnancy was made. Operation was thought of, but was abandoned, partly on account of the condition of the patient, and because the tumor, which had suddenly appeared, was entirely due to the rupture. Cushier says: "During the next few days there was a most marked improvement. The tympanites entirely subsided, and pain was completely controlled . . . the tumor could now be felt as a circumscribed mass . . ." After

[2] Transactions of the American Gynecological Society, 1888, p. 391.
[3] Ibid., 1884, p. 167.

this, fearing that the embryo *might posssibly* be still living, although the evidence was against this, and the patient was fast getting well, a faradic current was used, and now, forsooth, this is claimed as an electrical cure. It was clearly a case of spontaneous cure.

The case of Harrison,[1] which was seen by T. Gaillard Thomas, was a very similar one. Harrison himself says that the fœtus was dead when the treatment began, and he protested against its use—another case of spontaneous cure for which electricity has assumed the credit.

Cocks[2] called T. Gaillard Thomas to see a woman who had menstruated last on December 13, 1883. About the middle of January she began to suffer from pain, nausea, and vomiting. On March 27th, when seen by Thomas, a tumor about the size of a man's fist was discovered to the left of the uterus, and gave the sensation of a tense sac filled with fluid. The following day, or about three and a half months after the last menstruation, the faradic current was passed, and was applied daily for eight days with no change either in the condition of the tumor or the patient. Two weeks later galvanism was begun, sometimes with and at other times without ether, and was continued for eight or nine days, at the end of which time it was found that but little change had taken place. This was at between four and five months. On September 15th, about nine months after the beginning of the attack, it is said: "The pains were much less severe in character, and, though occasionally paroxysms occur, yet they are less violent than formerly, and much less frequent. . . . On examination the tumor is still found, but decidedly smaller, less tense, and less painful on pressure." From the history of this case there is not the slightest possibility of its having been a case of ectopic gestation; even Thomas says: "I freely confess that I am not entirely positive about the correctness of my diagnosis," and I think anyone who will carefully read the details as he gives them will quite agree with him in his doubt.

Lambert and Jones[3] record a supposed case of ectopic gestation which T. Gaillard Thomas saw in consultation. I will only remark that all the evidence of this disease being present is contained in an extremely unsatisfactory history. At the consultation Drs. Thomas and Jones pronounced the case one of ectopic gestation, her attending physician, Dr. Lambert, was in doubt, and Dr. Fordyce Barker rejected the diagnosis. In the words of Thomas, "the majority ruled," and the electrical treatment was instituted. The woman went home to the country at the end of ten days and at the last examination had still a pelvic tumor as large as a hen's egg. Is the profession ready to accept obediently that diagnosis? I think not.

The two cases of Allen[1] are both more than doubtful. In the first one the history of ectopic gestation is far from convincing, and three years after the treatment there was a well-defined tumor, the size of a large fist, very little if any smaller than before treatment. The second case is even more unsatisfactory from a diagnostic point of view, and the tumor still existed of almost its original size when Allen reported the case.

In the case that Wilson[2] reports, he himself says that he is "not satisfied it was a case of extra-uterine pregnancy." Dr. Howard saw the patient and was opposed to the diagnosis. There is no need to produce more evidence on this point. Any fair-minded, experienced man who will go thoroughly over the detail of these cases will soon become convinced that a large number, if not the majority of them, were mistakes in diagnosis. They at least are so dubious that they should have no place in scientific discussion.

After the preceding it is needless for me to say that I am strongly in favor of the treatment of extra-uterine pregnancy in its early stages by laparotomy, whenever and wherever diagnosed or strongly suspected. When we carefully analyze the cases which have been treated by electricity, eliminating those which are plainly mistakes in diagnosis, or of too doubtful a nature to be of any scientific value, and then place the failures and dangers of the treatment by the side of the remaining (or even by the side of the total number claimed by the electricians), the proportion of disaster is so overwhelming in comparison to those of laparotomy, that to my mind but one conclusion is rational.

In closing I wish to direct attention to the fact that two of the gentlemen who were among the most ardent admirers of the electrical treatment a year ago, have at last given up their idol. In 1889, Dr. E. E. Montgomery[3] said: "Electricity affords an agent for the destruction of fœtal life, which experience discloses can be relied upon for the arrest of development and the speedy and safe cure of our patients." In 1890,[4] he says: "I have been led to change my mind by this case, and another in which Dr. Baldy assisted me. This case with the last one has shaken the faith I had in the use of electricity."

Dr. George J. Engelmann[5] says that he had for-

merly urged the use of electricity in this disease, but he adds: "Increased experience has caused me to waver, and a case recently reported by Dr. Mooney, of this city, has appeared to me so convincing an argument in favor of *immediate operation* at *whatever period* extra-uterine pregnancy may be detected, that I am now an earnest advocate of surgical interference in all such cases."

THE TREATMENT OF FAILING CIRCULATION, WITH SPECIAL REFERENCE TO THE USE OF STRYCHNINE.

By C. S. BRADFUTE, M.D.,
DEMONSTRATOR OF THERAPEUTICS IN JEFFERSON MEDICAL COLLEGE; MEMBER OF THE NEUROLOGICAL STAFF OF THE PHILADELPHIA HOSPITAL.

When a physician is confronted by a case in which there is either sudden, gradual, or threatened failure of the circulation, the pregnant question arises—What is he to do? Naturally, his first thought is of some drug which, either from his own experience or that of others, he knows has been successful in combating or postponing this formidable complication, and the remedy he most desires is one that will act promptly and, as nearly as possible, entirely upon the circulatory apparatus. His judgment in the selection will be guided, if he be not merely an empirical therapeutist, by the cause of the cardiac weakness, the disease and condition of the patient, and the physiological action of the drug. It may seem unnecessary to make this preliminary statement, or even to broach the subject at all, to those whose high positions as teachers of medicine give them unlimited opportunities for experience and observation, and may even seem truistic in view of the fact that most of the matter here discussed can be found in so many text-books. But when it is considered that the average practitioner is prompted to request a consultation when this symptom begins to show itself, and that, as a matter of fact, comparatively few are able to cope with it, the writer may be pardoned if he omits an apology. He submits this paper with some diffidence, to invite a discussion upon this important subject, and in the hope that it will suggest to the minds of those who are familiar with the treatment of so-called heart-failure the usefulness of a publication of their knowledge of it.

There are numerous instances of the heart ceasing its function when it cannot be said that life would have flown under proper treatment, and it is in these cases that there is shown either the lack of proper remedies or the absence of a sufficient amount of medical skill, if not negligence. As previously stated, the remedy should act upon the circulatory system, and in a way that will increase the strength of the cardiac contraction and promote the rapidity of the circulation; and upon other parts of the organism it should not have any, or, at least, only a minimum, antagonistic concomitant action, which would tend to annul or counterbalance the prime effect upon the heart.

A glance at the physiological action of the cardiac tonics will show that some of them have a very disagreeable behavior in this respect, and in none is it so well marked as in the case of digitalis, which is generally adopted as an efficient agent. Quoting the words of an eminent writer, digitalis "prolongs the diastole and increases the vigor of the systole," an effect most desirable, because it gives the ventricles time to fill and to expel a maximum amount of blood into the lungs and arteries, but, unfortunately, it at the same time contracts the arterioles and raises the blood-pressure, thus lessening the rapidity of the blood-flow and preventing a proper washing out of waste products from the tissues. In addition to this, if large doses be given, it impairs the irritability of the sensory and motor nerves and muscular fibres, and interferes with reflex action, effects that cannot fail to retard nutrition. Clinically it has been found unsatisfactory in those low states of the system brought about by high temperature and degeneration of the muscular tissues—notably of the heart itself—such as are found in typhoid fever. Recently a scientific teacher of therapeutics was quoted as recommending that digitalis be employed in typhoid fever, and that he had had most excellent results from its use. It is difficult to understand this opinion, as the same writer states in his book that he has seen digitalis produce, even in therapeutic doses, a dicrotic pulse, and numbers of authorities have, both by their writings and lectures, condemned it. The late Dr. James H. Hutchinson was very pronounced in his opinion against the employment of the drug in fever, and once told the writer that he knew of several cases of sudden death occurring in the course of fever that were unquestionably due to the digitalis administered. In the failure which accompanies simple organic disease of the heart itself, and in that which follows the shock due to hæmorrhage and similar conditions, digitalis is the proper remedy; but in the class of cases mentioned above it does not fulfil the requirements. The slowness of its action precludes its use in acute heart-failure, for, though given hypodermically, it is from two to four hours before its peculiar effect is manifested. Clearly, then, digitalis should be employed in only a limited class of cases, and is not the drug for the majority of emergencies.

Ammonia has been spoken of as the most powerful cardiac stimulant known, but its action is transient and of short duration. In some cases it does not act well. Wood speaks of it as being most serviceable in purely functional cardiac failure, and

as not a reliable agent in that accompanying the adynamic fevers. To obtain from it a satisfactory effect it must be administered at short intervals, from every half-hour to one hour, and an insuperable objection to it is the fact that it cannot be used hypodermically without producing an inflammation at the site of the injection; and, in a disease like typhoid fever, fatal sloughing might result. It can be administered by the veins, but this is always a dangerous procedure, and it is doubtful if it be effective, as strong alkalies injected into the circulation of animals destroy the red corpuscles. It possesses the advantage of not being followed by the depression of the nervous system which constitutes so objectionable a feature in the case of alcohol, but from its chemical properties it is difficult to use in states of unconsciousness.

Atropine is justly regarded by many as a cardiac stimulant, and Harley has highly recommended it; but it is really more of a respiratory stimulant, and is only adapted to certain cases. Bartholow is inclined to doubt its usefulness in cardiac failure, since it exhausts the irritability of the heart ganglia; but, since the preliminary period of stimulation is well marked, he advises its use in temporary depression of the heart's action. When given in large doses it locks up the secretions and must necessarily interfere with nutrition and lessen the excretion of waste products, and, on this account, cannot be safely employed in uræmia.

Alcohol is a safe and effective heart-stimulant when intelligently used, and is probably the best general tonic in the list. It possesses the advantage of being comparatively non-toxic, and can be administered for a longer period than some of the other heart-tonics, without deleterious effects. Its influence upon the processes of nutrition renders it especially adapted to those long-continued cases of gradual circulatory failure that are encountered so frequently in the low fevers. But its effectiveness in cases of sudden or profound cardiac failure occurring in the course of acute maladies, such as pneumonia, in which large amounts must be given, either by the mouth or hypodermically, is open to doubt, since the profound depression that follows its exhibition in large doses must certainly conduce to an unfavorable result. It may be more correctly regarded as prophylactic rather than as an active combative agent.

Caffeine and cocaine have lately been much used as heart stimulants, and they are of undoubted value in simple weakness, when there is no reason to suspect that the weakness is a premonition of beginning failure. The action of the former is fugacious, owing to its chemical instability, and the writer has seen the delirium of typhoid fever markedly increased by cocaine. They, like alcohol, may be better classed as prophylactics.

Nitroglycerin is an active remedy in certain cases in which the heart is slow and weak. It paralyzes the inhibitory centres, dilates the arterioles, and with the increasing heart-action thus induced the circulation is rapidly promoted. A very interesting article on the comparison between the action of this remedy and digitalis lately appeared in the *British Medical Journal*, which serves most aptly as evidence that neither drug can be depended upon in all cases. The transitory impression made upon the heart by nitroglycerin compels the drug to be given in frequently-repeated doses, and its powerful toxicity renders it too dangerous for general employment. The writer administered it once with most happy results in a case of shock due to traumatism, the pulse increasing in three and one-half hours from 40 per minute to 78. In such instances there is, of course, doubt as to the part played by the medicine. A rapid heart would be a contra-indication to its use.

Ether acts quickly and is effective in some instances of cardiac failure following traumatism, but the effect is not sustained, and it is not advisable to give it for more than a short time.

Strophanthus, sparteine, convallaria, and adonis vernalis have not as yet been sufficiently studied to be considered.

In the array of remedies that are criticised above it is seen that none of them fulfils the indications for relief that are presented by most cases of heart-failure, without at the same time exhibiting deleterious counter-effects. An agent which will sustain the circulation must not interfere with the resulting good effects of such action by any secondary manifestations, and until one can be found that will behave in this manner the problem must be met by such a combination of remedies and methods as will most nearly resemble the desired drug.

The writer considers strychnine, if not the best, at least one of the best, cardiac stimulants available. A study of its physiological action undoubtedly shows that it, too, has objectionable features, but fortunately they can, to a certain extent, be mitigated by the conjoint use of other remedies. Strychnine is very diffusible; it acts quickly, and the effect is sustained. When a medicinal dose is administered hypodermically the heart at once responds by an increase in the strength of its movements, the arterioles contract, and the blood-pressure rises. At the same time the irritability of the sensory and motor nerves and the excitability of the muscular tissue are greatly increased, thus promoting nutrition-changes and mechanically favoring a rapid blood-current. A spasmodic contraction of the renal capillaries is likely to occur if large doses

are given, but the interference with the kidney secretion can be obviated by diuretics having a selective action upon the urinary organs. Lately strychnine has been strongly recommended by some eminent observers as a reliable agent when other members of the group of cardiac tonics are contraindicated, and to the writer, who used it a great deal while resident physician in the Pennsylvania Hospital, it has proved very satisfactory. The stimulation is not confined to the circulatory system, but is general, and in many respects very much resembles the effects of heat. Its characteristic effect upon the spinal cord no doubt tones up, so to speak, through the sympathetic nerves, the digestive function, which with the diffused stimulation of the circulatory system must certainly result in a supply of better blood to the nerve-centres, and consequently to promotion of the vital functions.

A curious fact in connection with the action of strychnine is that the weaker the circulation the larger is the amount necessary. Its action seems to be in a way neutralized by the causes inducing the weakness, requiring in some instances rapidly-increasing doses to maintain the effect. Dr. C. B. Penrose informs the writer that he has given hypodermically as much as two grains of the sulphate of strychnine in twenty-four hours, with the result of successfully tiding the patient over a crisis.

This paper is intended as a preliminary to a more complete consideration of the usefulness of strychnine, and in a future article, now in course of preparation, the writer hopes to be able to indicate the extent and class of cases in which it can be effectively employed.

MEDICAL PROGRESS.

Immunity against Tetanus and Diphtheria. — In the *Deutsche medicinische Wochenschrift*, December 4, 1890, Drs. Behring and Kitasato publish the results of their experiments on rabbits and mice regarding the production of immunity in them against tetanus and diphtheria. The results regarding the former disease were the most definite.

It was found that immunity is based on a power communicated to the liquor sanguinis, apart from the cells, to make innocuous the toxic substances causing tetanus. The method of imparting this property to the liquor sanguinis is not given, but its future publication is promised.

Not only did the animals treated by the method of the authors prove immune, but the serum of their blood when injected produced immunity in other animals.

If 5 c.cm. of this serum were allowed to remain in contact with 1 c.cm. of tetanus culture for twenty-four hours, a dose of the tetanus virus three hundred times as large as that which is ordinarily fatal could be introduced without causing any harm. It was also found that even during the progress of the disease the new method of treatment favorably influenced its course.

It is to be inferred from the paper that similar, though less definite, results were obtained with diphtheria.

It remains to be seen if these methods can be applied to man.

In the same journal, December 11th, Behring publishes the results of his researches regarding the production of immunity against diphtheria in animals. The experiments have so far led to no practical results, but are interesting to the pathologist and experimental therapeutist.

The author mentions five methods of producing immunity in animals susceptible to the disease. The first four are based on Pasteur's methods, and depend on the action of certain products of tissue-interchange obtained in the cultures or in the living animal organism.

The fifth method is original, and consists in the application of an inorganic substance, which in these experiments was peroxide of hydrogen (H_2O_2). That certain chemical agents have the power to impart immunity in other infectious diseases appears to be established by Kitasato's results in the prevention of tetanus by the previous application of solutions of trichloride of iodine, which are mentioned in the paper.

It is noteworthy that the animals made immune lost their power of resisting the virus after the repeated use and increased doses of the latter.

The facts that certain animals possess an immunity against diphtheria, and that the blood-serum of guinea-pigs which have been made immune has the power to neutralize the toxic properties of diphtheria virus, led the author to the idea that the immunity rested on certain properties of the liquor sanguinis. This theory stood the test made with the tetanus virus as previously described.

Of great importance is the fact mentioned in the second paper, that even if several limbs of a mouse are tetanically convulsed, and death under ordinary circumstances would be expected in a few hours, the experimenters invariably succeeded in curing the tetanus completely in a few days; a fact which shows the possibility of curing very acute cases of the disease.

A Case of Death from the Use of Bromoform in Whooping-cough.—In the *Journal de Chirurgie et de Pharmacologie*, November 20, 1890, Nauwalaers details a case in which bromoform was given for a cure of whooping-cough with a fatal result. A child aged one year and three months, presenting all the characteristic symptoms of whooping-cough, was ordered 2 drops of bromoform in an alcoholic solution eight times a day. At the end of a week there was no amelioration in the symptoms, and 3 drops eight times a day were ordered, the case being carefully watched. Three days later it was noted that the treatment was still of no avail, and the case persisted for another week without amelioration. Finally 12 drops of bromoform were given. Seven days later the child after receiving its regular dose passed into a state of profound stupor with great pallor, collapse, complete muscular relaxation, shallow respirations, feeble circulation, immobility of the pupils, and insensibility of the cornea. Notwithstanding injections of ether and the employment of artificial respiration, with electrical stimulation of the phrenic nerve and inhalations of nitrite of amyl the patient became much worse, and

finally, owing to the cyanosis which was present and the obstruction to the breathing which seemed to exist near the epiglottis, tracheotomy was performed, when it was noticed that the air which was expired possessed a pronounced odor of bromoform. Amelioration of the symptoms followed the operation, but the muscular relaxation persisted. Later all the early symptoms returned and hypodermic injections of caffeine and hot applications were resorted to. It was noted that the hypodermic injection rapidly produced a local ecchymosis, and shortly after this the child expired.

At the autopsy the pericardium was found to be normal and the pleural cavity free from adhesions. The lungs were of normal color, but contained a large quantity of liquid in the bronchial tubes, which was not purulent. The stomach was reddened, but otherwise apparently normal, but the duodenum was congested. The kidneys and spleen were unaffected. There was a large quantity of red liquid under the dura mater, although the pia mater was normal. The lateral ventricles of the brain were distended. It will be seen, therefore, that the changes produced by tne poison were sufficient to explain the fatal result. The author then details the clinical evidence in favor of the drug, and urges the conclusion that while bromoform is of great value in the treatment of whooping-cough, exercising both a curative and palliative action, it corresponds very closely with chloroform and is dangerous. Finally, that the treatment of poisoning by this drug should consist in the evacuation of the stomach by the use of emetics, in the use of artificial respiration and cardiac stimulants, and, if necessary, tracheotomy with inhalations of oxygen.

Masturbation in an Infant.—At a recent meeting of the Medical Society of London, DR. BEEVOR showed a male infant eleven months old who had been in the habit of masturbating since the age of four months. Erections were produced and at times a glairy mucous was said to exude from the urethra. The child had been circumcised, and bromides had been given, but without effect on the habit. No cause for the condition could be ascertained. There was no stone in the bladder; the urine was alkaline, but contained neither albumin nor phosphates.—*British Medical Journal*, November 29, 1890.

Granular Conjunctivitis.—The following treatment is recommended by TENLON in cases of granular conjunctivitis of a persistent type, with much photophobia. He orders one drop of the following collyrium to be instilled into the eye morning and night:

℞.—Distilled water . . . . ½ ounce.
Neutral sulphate of atropine . 1½ grains.

In the evening he introduces into the eye a very small piece of the following ointment:

℞.—Calomel, pure and thoroughly pulverized . . . . } 2 drachms.
Vaseline . . . . . 1 drachm.

He also finds it of service during the day to apply fomentations for as long periods as possible, consisting of the decoction of chamomile as hot as can be borne. At the same time it is well to administer internally cod-liver oil, syrup of the iodide of iron, and general tonics.

Treatment of Pneumonia.—In the earliest stage of pneumonia DR. EUGENE GRATZER (*Therapeutische Monatshefte*) prescribes a few large doses—4 grains each to adults—of calomel at intervals of three or four hours, with the best results, the fever being reduced and the disease running a mild course. In cases which are further advanced his favorite remedy is antipyrine given in 4-grain doses three times daily. He also prescribes as an expectorant the following:

℞.—Decoction of senega . . 2½ drachms.
Extract of opium . . 1½ to 4 grains.
Syrup of althea . . . 5 drachms.—M.
Dose, one teaspoonful.

In young children opium and morphine are avoided and cherry-laurel water is given.

During convalescence digestion is stimulated by the following mixture:

℞.—Dilute hydrocyanic acid . 15 minims.
Water . . . . . 4 ounces.
Spirit of nitrous ether . . 1 drachm.
Syrup sufficient to make . 6 ounces.—M.
One tablespoonful every two hours.—*Provincial Medical Journal*, December, 1890.

Myxœdema Treated by Thyroid-grafting.—At a recent meeting of the Medical Society of Paris the notes of a case upon which MR. WALTHER had operated for myxœdema by transplanting the thyroid of an animal were read. The operation was performed on September 3, 1890, the patient being a woman about forty years old. The graft was placed under the right breast and the wound healed by first intention. On September 6th, menorrhagia, which had been very troublesome, ceased. The amelioration in the patient's general condition is no less striking. The puffiness of the face has diminished and the pseudo-lipomatous condition is much less marked. It is in the functional disturbances, however. that the improvement has been greatest. Her speech has become much more clear and she walks more easily.—*Lancet*, November 29, 1890.

An Application for Gout.—The *St. Louis Medical and Surgical Journal* quotes the following:

℞.—Flexible collodion, Ether } of each . 5 parts.
Salicylic acid . . . . 4 "
Muriate of morphine . . . 1 part.—M.
This should be applied to the affected toe.

Arsenic in Phthisis.—LADENDORF employs the following solution of arsenic in hypodermic injections to reduce the fever of phthisical patients:

℞.—Fowler's solution . . . 30 minims.
Distilled water . . . . 2½ drachms.
Hydrochlorate of cocaine . . 1 grain.

Of this half of the contents of an ordinary hypodermic syringe is injected. This injection is to be employed once every third day. It seems probable that this method possesses no advantage over the use of arsenic by the mouth.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

HYPNOTISM AS A CLOAK FOR CRIME.

FOR the first time, we believe, in the history of medical jurisprudence hypnotism has been brought forth as an explanation of and a defence for crime. The Eyraud-Bompard trial, just closed in Paris, has a lasting interest far exceeding that which attaches to its merely sensational and revolting details. Both in its scientific and its judicial aspects the trial was an extraordinary one, and for its scientific features alone will be long remembered and referred to. It will, no doubt, have a permanent influence upon the jurisprudence of insanity and crime, not only in France, but in other countries.

The reasons for this are not altogether simple, and will bear some examination in detail. The first and chief reason, in our opinion, is the fact that a kind of mysticism has hung about this word "hypnotism," not only in lay, but also in medical, parlance. This trial will help to dispel the mysticism. The word, and what it stands for, have not been subjected, even in medical circles, to a strict criticism; while in extra-medical circles, as in the newspapers and in daily conversation, the term has been given a dignity and significance which it by no means deserves, and which make it, and the ritual for which it stands, a ready means for mystification and fraud. It is not to be wondered that the time has come for this convenient ceremonial to be made the excuse for crime, just as it has more than once pandered to vice and defrauded the credulous.

The fundamental fact underlying hypnotism is "suggestion." All else is mere by-play—the mere histrionic tricks or draperies which are meant to add force and efficacy to that one central act. Hypnotism, in other words, is simply the power which one mind has to instill certain dominant ideas or purposes into another mind; hence it is as old as the human race, and has been in operation in one way or another ever since man first tempted man to evil or persuaded him to good. Doubtless in some very "susceptible" persons some unusual psychological effects may be procured. Such persons are usually hysterical, semi-hysterical, or credulous—a class fond of the marvellous, with little ability or wish to rely upon themselves in thought and action, and especially fond of any dramatic scene which includes themselves as conspicuous actors. Hence, it is difficult to judge in some of these cases how sincere the subject is, or how far he or she is merely playing a part. Even the accomplished mind of Harriet Martineau was so weak as to receive suggestions of mesmeric influence, and attributed to this a power that which was simply a revived moral purpose within herself. So the criminal Bompard has sought in vain to attribute to hypnotism her own evil devices. In the hands of the physician who attempts with mirrors, bright objects, and a meaningless rite to impose upon the credulous or the sick the process comes perilously near quackery; and on the witness-stand his testimony must be open to grave suspicion or doubt.

The Eyraud-Bompard trial displayed this quackery to its extreme limits, and exposed it to the gaze and criticism of the world. No one doubts that Bompard received evil suggestions from Eyraud, and that Eyraud received evil suggestions from Bompard. Thus conspiracies and crimes have ever been hatched. But what student of a rational psychology will believe that Eyraud stole the "will" of the luckless Bompard, put her under a "hypnotic spell," in which she led a "dual existence," and so with her wrought out a scheme of murder, concealment, theft, and flight (involving many details of preparation, a trip to London, etc.), in which hypnotic state this Parisian demi-mondaine was unconscious of evil and without blame?

Some features of the trial are noteworthy. The

medical witness who supported the theory of hypnotism was on the stand, so it is reported, four hours, and was allowed by the court the greatest latitude. The presiding judge, however, refused very wisely to permit any hypnotic *séance* to be had with the prisoner in open court. The verdict, in spite of the hypnotic theory, was a just one, and the mercy extended to the female prisoner all that her sex and age could expect.

SPECIAL ARTICLES.

THE PRODUCTION OF IMMUNITY FROM DIPHTHERIA.

BY E. A. VON SCHWEINITZ, PH.D.,
AND
W. M. GRAY, M.D.,
OF WASHINGTON, D. C.

IN view of the interest which is at present being taken in biochemical research, and the impetus which has been given to investigation in this line, we deem it advisable to make a preliminary statement in regard to the work which we have conducted in producing immunity from diphtheria in animals. The disease-germ which we have used is Klein's bacillus, which is probably identical with the Klebs-Löffler bacillus. Without going into details, we may state that we have succeeded in obtaining a chemical substance which renders guinea-pigs treated with it insusceptible to diphtheria upon subsequent introduction of the strong virus into the system, while the control guinea-pigs died in from twenty-four to forty-eight hours.

We further believe that the experiments being made will demonstrate that we have a substance which will serve to control or prevent diphtheria in man. That methods for the treatment of typhoid fever, tetanus, and other contagious diseases can be worked out in a similar way is undoubtedly true, though it may require a long series of experiments to demonstrate this conclusively.

DECEMBER 24, 1890.

BRIEF NOTES ON NINE CASES TREATED BY KOCH'S LYMPH.

BY EDWARD CHARLES WENDT, M.D.,
OF NEW YORK.

SEVEN of these cases are under observation at the St. Joseph's Orphan Asylum and two at the New York Infant Asylum. These notes are necessarily brief, and must be regarded as in the nature of a preliminary communication. The lymph was obtained through the courtesy of Dr. L. Weber, of New York.

SMALL INITIAL DOSES.—Most of the cases being those of young children, the initial dose has generally been only one-quarter of a milligramme—*i. e.*, 0.00025 gramme. It is to be remembered that in using Koch's lymph we are employing a very powerful agent, and that we are still in the experimental stage of clinical investigation regarding its efficacy. It has not been demonstrated that the larger the dose the more powerful the effect for good; while, on the other hand, the possible harm would certainly appear to be in direct proportion to the quantity of lymph injected. The smallest dose that is capable of producing a decided reaction ought to be regarded as sufficient to excite those tissue-changes upon which the curative effect of the lymph is supposed to depend.

These remarks are by no means offered in a spirit of criticism of those who employ the usual 0.001 m. initial dose. They are merely intended to call attention to the possibility of benefiting our patients without incurring the risk of unpleasant disturbances.

TIME AND INTENSITY OF REACTION.—In all undoubted cases of tuberculosis the injection of Koch's lymph was followed by a febrile reaction. But the time of its first appearance, as well as its intensity and duration, was subject to wide variations. The highest temperature thus far recorded has been 104.3° F. Subnormal temperatures have not been observed. Alarming symptoms have not developed, although the malaise and restlessness of some of the children have been very marked. Signs of local irritation of moderate intensity have appeared at the site of inoculation in two cases. The injections have been made into the subcutaneous tissue of the abdomen, back, or thigh, preferably the first-mentioned region.

CASE I. *Strong hereditary predisposition to phthisis.*—Girl, aged eleven years. Parents both died of consumption when comparatively young. Her only sister is now in the last stage of phthisis. This girl is pale and delicate in appearance, chest flat, cervical glands very slightly enlarged, no physical signs relative to lungs, no cough. Small eater.

December 24, 1890, 2 P.M. First inoculation, 0.00025 gramme. No reaction. Temperature normal.

25th. Everything normal.

26th, 11 A.M. Second inoculation, 0.0005 gramme. 2 P.M., temperature 99.2° F.; at midnight, 98.2° F.

27th, 11 A.M. Third inoculation, 0.001 gramme. 2 P.M., temperature 101° F.; 9 P.M., 99.2° F.

28th. Fourth inoculation at noon, 0.001 gramme. Temperature did not rise above 99.3° F.

29th. Fifth inoculation at noon, 0.002 gramme. At 3 P.M., rise in temperature to 100.8° F.

The peculiar interest attaching to this case is due to the fact that our ordinary methods of examination would not permit us to say more than that the girl was likely to have phthisis later on. But if the

occurrence of distinct reaction after the injection of Koch's lymph is really pathognomonic of the presence of tubercle, then this girl is already in the first stage of tuberculosis. And it is precisely in this class of cases that the curative effect of the lymph will probably find its widest sphere of applicability. Until now this girl has developed no cough. In fact, apart from temporary malaise and a decided febrile reaction, the lymph has produced no appreciable effect whatsoever.

CASE II. *Ozæna scrofulosa, and lymphadenitis of neck.*—Girl, aged nine years, strumous. Ulcerating eczema of nose, recurrent phlyctenular keratitis.

December 24. 0.00025 gramme injected: no reaction.

25th. 0.0005 gramme, followed by highest temperature of 98.3° F.

27th. 0.001 gramme, followed by distinct reaction. Temperature 100.3° F.

28th. 0.0015 gramme, followed by rise of temperature to 102.2° F.

29th. Temperature in morning 99° F. Inoculation of 0.002 gramme at noon. At 3 o'clock P.M. the temperature had risen to 100.2° F.

This girl developed considerable cough, although an examination of the lungs before treatment was absolutely negative. The keratitis rapidly disappeared. Around the nose large red blotches appeared, which later resembled the erysipelatous reaction seen in lupus.

CASE III. *Hip-joint disease.* (*Service of Dr. F. Kammerer.*)—Girl, aged three years. Left hip-joint flexed, adducted, and fixed. Limping since one and a half years old. Previous treatment by extension. Abscess opened some time ago.

December 26. First inoculation of 0.00025 gramme at noon. At 2 o'clock P.M. temperature 99.3° F. At 4 o'clock P.M. temperature 100° F.

27th. 0.0005 gramme injected. Reaction to 100.3° F.

28th. 0.001 gramme injected. Temperature remained stationary at 100° F. all day.

29th. 0.0015 gramme injected. Temperature rose to 102° F. in three hours. No signs of local reaction at hip-joint up to this day.

CASE IV. *Hip-joint disease.* (*Service of Dr. F. Kammerer.*)—Girl, aged five years, taken ill about one year ago. Gradual development of symptoms. Extension treatment at first successful. Relapse this fall. Has failed of late.

December 26. First inoculation of 0.0005 gramme. Highest reaction, temperature 100.3° F.

27th. Injection of 0.001 gramme. Reaction to 102.2° F.

28th. Injection of 0.001 gramme. Reaction to 102.0° F.

29th. Injection of 0.0015 gramme. Temperature three hours after injection 101.8° F. It should be stated that in this case the temperature did not remit to the normal point, but fluctuated between 99° and 100° F. even during the time when it should have been normal. No local reaction at hip-joint. Movements more painful than at beginning of treatment by inoculation.

CASE V. *Tubercular glands in neck and submaxillary region. Scrofulous affection of eyelids and nose.*—Girl, aged eleven years. Two years ago severe chorea, which yielded to large doses of arsenic (up to 15 drops of Fowler's solution three times daily). Has lost flesh lately. A few suspicious râles at both apices.

December 27. First inoculation of 0.0005 gramme at noon.

Temperature at 2 P.M. 100° F.; at 4 P.M. 101° F.; at 6 P.M. 102° F.; at 9 P.M. 103.2° F.

28th. Second inoculation at 1.30 P.M. of 0.00075 gramme. Temperature was 101° F. in the morning (*i. e.*, incomplete recovery from reaction). At the time of this injection it was said to be normal, although I did not verify it.

Temperature at 3 P.M. 102° F.; at 5 P.M. 103° F.; at 7 P.M. 103.3° F.; at 9 P.M. 104.2° F.; at 12 P.M. 104.3° F.

Scarlatinoid rash all over body developed after second injection. Glands in the neck not larger than before treatment, and not painful. Feels sleepy and dull.

29th. Temperature at 9 A.M. 101.2° F.; at 12 noon 101° F. No inoculation to-day.

CASE VI. *Incipient phthisis.*—Girl, aged sixteen years. Mother died of consumption. Has been liable to "colds" for years. Supraclavicular spaces sunken in, chest flat. No emaciation. Slight cough. General condition fairly good.

December 27. First inoculation of 0.0005 gramme. Slight reaction to 99.3° F.

28th. Temperature normal at 8 A.M. Second inoculation at noon, 0.001 gramme.

By 9 P.M. temperature had risen to 101.3° F.

Scarlatinoid rash over body.

29th, A.M. Temperature normal. Injection 11 A.M. of 0.002 gramme.

Temperature at 3 P.M. 102° F. Has developed much cough and expectoration.

CASE VII. *Scrofula.*—Girl, aged five years. About one year ago convulsions and signs of meningitis. As she recovered it was held to be simple meningitis, although the symptoms were those of the tubercular variety. Also had pneumonia in 1889.

At present is pale and delicate in appearance. Glands at neck enlarged. A few râles (bronchitic) on left side of chest.

December 28. First inoculation of 0.00025 gramme. No reaction.

29th. Second injection of 0.0005 gramme. Reaction to 100.8° F.

The two remaining cases are under observation in my service at the New York Infant Asylum.

CASE VIII. *Tubercular (?) lymphadenitis of neck.*—Infant, aged nineteen months. In the latter part of November, 1890, Dr. Townsend removed some broken-down glands from right side of neck. Thick, bulging cicatrix. Some glands still enlarged. Healthy-looking, plump baby.

First inoculation, December 24th, 2.30 P.M.,

0.00025 gramme. No reaction, except slight rise of temperature following day to 100.4° F.

Second inoculation, December 26th, 0.0005 gramme. Temperature rose to 100.6° F.

Third inoculation, December 29th, 0.001 gramme. (Record not complete.)

CASE IX. *Incomplete resolution after pneumonia.*—Colored woman, aged twenty-three years. Condition previous to admission "delicate." Family history unknown. About the middle of October, 1890, she had an attack of pneumonia, from which she has not recovered. Temperature during height of attack not above 103° F. Signs of consolidation persisted, even after fever subsided. Cough, with expectoration, occasional night-sweats, and deterioration of general health were observed. During the month of December her temperature became almost normal, no hectic. Two weeks before first inoculation highest temperature was 99.5° F.

First inoculation, December 24th, 2.15 P.M., 0.00025 gramme, temperature normal at time. Slight reaction to 99.6°, but subjective symptoms more marked.

25th. Slept poorly night before. Anorexia, nausea, malaise, pain in head and joints. Coughs much more than before injection. Later she vomited twice. Temperature that afternoon (*i. e.*, twenty-four hours after first inoculation of one-fourth milligramme), 101.2° F.

26th, A.M. Feels much better after a good night. Second inoculation of 0.0005 gramme, followed by milder reaction. Temperature 100.6° F. Considerable cough. By December 29th temperature back to normal. On that day third inoculation of 0.001 gramme. The area of chest-dulness is larger, but auscultation shows no appreciable change.

This case seems interesting on account of the race of the woman. So far as I know, the lymph has not hitherto been tried on colored people, and the decided reaction obtained after a minute dose, may give a hint as to caution in using it in negroes.

It was noticeable, also, in this case, that the defervescence of the febrile reaction was more gradual than would appear to be the rule.

712 MADISON AVENUE, December 29, 1890.

REVIEWS.

A COMPEND OF HUMAN ANATOMY, INCLUDING THE ANATOMY OF THE VISCERA. By SAMUEL O. L. POTTER, M.D. Fifth edition. Revised and enlarged. Philadelphia: P. Blakiston, Son & Co., 1890.

THE appearance of the fifth edition of Dr. Potter's book upon anatomy proves not only that he is a successful teacher, but also that this is another one of his works which does him credit and gladdens the heart of his publisher. Though it is marred by a rather lengthy and unnecessarily eloquent dedication, the style of the rest of the book is so clear as to permit of no misunderstanding on the part of the student, and there is no reason to doubt that the fifth edition will become even more popular than the previous issues.

RHEUMATISM AND GOUT. By F. LEROY SATTERLEE M.D., Ph.D. 12mo., pp. 83. Detroit: George S. Davis, 1890.

THE author of this brief essay writes with an earnestness born of personal experience. As he tells us in his preface, he was a martyr to the gouty and rheumatic diatheses, which he was able to overcome by the hygienic and therapeutic measures he here describes. There is, however, little that is original in his methods, and the book can be regarded only as a readable description of common-sense methods of treating two troublesome diseases.

ESSENTIALS OF DISEASES OF CHILDREN. By WILLIAM M. POWELL, M.D. Saunders' Question Compends No. 15. 12mo., pp. 222. Philadelphia: W. B. Saunders, 1890.

THIS book is arranged like the others of the series to which it belongs, and probably contains as much information upon the diseases of children as could be compressed in a book of this size. It is clearly written and has evidently been carefully prepared, and will doubtless prove useful to those whose want of time or of inclination prevents them from referring to larger works.

THE PHYSICIAN'S VISITING LIST FOR 1891. Philadelphia: P. Blakiston, Son, & Co.

THE fact that this visiting list has been published annually for forty years is sufficient guarantee of its excellence and popularity. In addition to the visiting list proper, it contains easily-accessible suggestions upon many of the emergencies that may arise in a physician's practice, and when he is too far from home to learn from his text-books the antidote for a poison that may have been swallowed, or the proper method of resuscitating a half-drowned person. True, he should know these things, but who does not occasionally forget, when he most wishes to remember? There are also dose-tables, tables of the metric system, a list of new remedies for 1890, rules for examining urine, a table for calculating the period of pregnancy, and other equally useful information. The arrangement for entering patients, visits, consultations, etc., is exceedingly simple, and the whole makes a thin, compact, and easily-carried volume.

CYCLOPÆDIA OF THE DISEASES OF CHILDREN, MEDICAL AND SURGICAL. By AMERICAN, BRITISH, AND CANADIAN AUTHORS. Edited by JOHN M. KEATING, M.D. Vol. IV. 8vo., pp. 1128. Philadelphia: J. B. Lippincott Company, 1890.

THE concluding volume of this already well-known work is devoted to diseases of the ear, eye, and nervous system, and to hygiene. It opens with an article of forty-nine pages by Dr. Charles H. Burnett on Diseases of the Ear in Children. A brief description of the anatomy and pathology of the ear is given, but the larger part of the article relates to diagnosis and treatment. The succeeding article, Affections of the Eyelids, Lachrymal Apparatus, Conjunctiva and Cornea, by Dr. G. E. de Schweinitz, will prove a most useful one to the general practitioner who is compelled to treat these diseases. The same may be said of the article on Diseases of the Eye, by Drs. Charles S. Turnbull and George M. Gould, and of that on Ophthalmoscopy; Local Diseases

and Functional Disorders of the Choroid, Optic Nerve, and Retina, by Dr. Charles A. Oliver. An interesting article of eighty-four pages on Physical Development is contributed to the section on Hygiene, under the joint anthorship of the Editor of the *Cyclopædia* and Dr. James K. Young. Full descriptions of the proper methods of developing the muscular system of children are given, and the paper is illustrated by a number of reproductions of instantaneous photographs of children and adults showing the mechanism of walking, running, etc. Another useful paper in this section is that on School Hygiene, by Dr. D. F. Lincoln. The article on the Construction of Children's Hospitals, by Dr. Lindley Johnson, seems almost unnecessary in a work of this kind, and, moreover, it is the most carelessly written article, so far as diction is concerned, in the four volumes. We are not sufficiently familiar with carpentry, masonry, and architecture to judge the correctness of the author's opinions. The two following articles, Juvenile Crime and Public Methods of Prevention and Reclamation, by J. Percy Keating, Esq., and Medico-legal Testimony, by Dr. Jerome Walker, are interesting and exceedingly instructive. Diseases of the Nervous System occupy more than one-half of the volume and include twenty-eight papers of more than ordinary merit; indeed, it is safe to say that no department of the entire *Cyclopædia* is more uniformly excellent. Among others there are articles on the Diagnosis of Diseases of the Nervous System, by Dr. Allan McLane Hamilton; Cerebral Palsies and Suppurative Meningitis, by Dr. Landon Carter Gray; Tubercular Meningitis, by Dr. A. Jacobi; Intra-cranial Tumors, by Dr. M. Allen Starr; Hereditary Ataxia and Locomotor Ataxia, by Dr. Charles L. Dana; Headache, by Dr. E. C. Seguin; and Insanity, by Dr. E. C. Spitzka.

We congratulate Dr. Keating and his publishers upon the successful completion of a work that no practitioner can afford to be without.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting of November 23, 1890.

DR. G. M. EDEBOHLS read a paper entitled

EXPLORATORY PUNCTURE OF THE FEMALE PELVIC ORGANS,

dealing with the differential diagnosis of slight enlargements, or "masses," which are situated either entirely within the pelvis, or which originate there and project but slightly above the brim of the true pelvis, and are recognizable only by combined abdominal and vaginal touch. As an aid in the differential diagnosis of such tumors, the author has systematically practised, for two years, a method of exploratory puncture of the female pelvic organs which he terms "abdominal puncture guided by combined vaginal and rectal touch." The method is practised as follows: The skin of the lower part of the abdomen is carefully disinfected. The middle finger of the left hand is passed into the rectum, and the index finger of the same hand into the vagina. With these fingers the ovary, tube, small tumor or mass is located. The finger in the rectum, if possible, reaches posteriorly to the upper limits of the mass, the finger in the vagina being applied to the lower limits. A point on the anterior abdominal wall directly over the centre of the mass is located by the carefully-disinfected fingers of the right hand. At this point a sterilized hollow needle is carried perpendicularly through the abdominal wall and the intervening tissues and organs into the centre of the mass. The fingers in the vagina and rectum fix the diseased structures, control the course of the needle, and guide it into that part of the mass which it is desired to puncture. An assistant draws the piston, while the operator's right hand firmly grasps the barrel of the syringe, thus steadying it and the needle.

The author has practised the method in more than seventy cases without having had the least untoward or disagreeable result. The important points of the procedure are (1) perfect asepsis, (2) immobility of the syringe and needle, (3) resistance of the temptation to bore about in the tissues with the needle.

The paper was discussed by Drs. A. F. Currier, A. H. Buckmaster, C. T. Jewett, A. P. Dudley, H. J. Boldt, H. C. Coe, and R. A. Murray. The consensus of opinion was against the operation. It was conceded that the method was certainly an ingenious one, and that it had apparently given good results in the hands of its originator. It was questioned whether there is any need of a diagnostic procedure which exposes a patient to the dangers of puncture of the intestines and peritoneum, with consequent peritonitis, and probably death, when the present good results are obtained by the much more satisfactory method of incision, if a diagnosis cannot be made without an operation of some kind.

DR. J. C. EDGAR made some remarks on

THE MANIKIN IN THE TEACHING OF PRACTICAL OBSTETRICS,

and exhibited a manikin and a number of appliances which are used by himself in teaching his class in obstetrics. The chief points made by the speaker were: (1) that, as a rule, it is a difficult matter to procure sufficient material, in the shape of puerperal women, for the education of the medical student; (2) that even if this were possible, the student could not study the mechanism of labor, and could have no guide in the application of the forceps, or the performance of any other operation in the pelvis; (3) that if students had thorough manikin training, with the fœtal cadaver, they would leave college equal to any emergency that might arise in the puerperal chamber.

DR. FLORIAN KRUG described the operation of

TRANS-PERITONEAL HYSTERORRHAPHY,

a new method of ventro-fixation of the uterus without opening the abdominal cavity. The method is only applicable to the cases of obstinate, movable retro displacements which have resisted every other form of treatment. The patient is placed in Trendelenburg's position, having been previously prepared for the operation with the same care as for abdominal section. A sound is introduced into the uterine cavity, while a tenaculum holds the anterior lip of the cervix, and a catheter is placed in the bladder. The assistant who is

trusted with these instruments now brings the uterus forward against the abdominal wall, no force being used. After selecting a suitable place to "ventro-fixate" the uterus, a very small incision is made in the linea alba. When the peritoneum is exposed, the finger is introduced into the wound and comes at once upon the fundus of the uterus. The assistant now indicates the position of the bladder and uterus by alternately moving the catheter and sound, and a needle, especially made for the purpose, is passed through the abdominal walls. After the needle has entered the abdominal cavity, it can easily be felt between the uterus and the peritoneum. The cutting edge on the back of the needle is now used to denude about one square inch on the anterior surface of the uterus, and the needle is then passed through the body of the uterus, and brought out at a place corresponding with the point of entrance. It is then threaded with a strand of silkworm-gut and withdrawn, bringing the end of the suture with it. The two strands are now tied, and are generally sufficient to close up the entire wound. As a rule, the operation does not require more than from five to eight minutes. The patient is kept in bed for from ten to fourteen days. The ligatures are allowed to remain for between four and six weeks, when on removal the uterus is found firmly adherent to the anterior wall in a normally anteflexed position. The operator's experience with this method is limited to six cases, all of which have done well, and the results so far are good.

CORRESPONDENCE.

BERLIN.

Observations on the Use of Koch's Lymph in the Berlin Hospitals.

SIR: The following are some points in reference to the use of Koch's fluid for the treatment of tuberculosis that I have gathered at the bedside in Berlin hospitals:

The remedy is dangerous, and must be exhibited with exceeding care in every case. It seems powerful for good; it is as potent for evil. The initial dose should usually range from one-half to one milligramme. Lupus-cases bear larger doses.

The repetition of the dose should depend not only upon the amount of reaction, but also upon the general condition of the vital powers during the next twenty-four hours. If there is extensive tubercular laryngitis be ready for a laryngotomy or tracheotomy. In such a case it is a small dose in mind and your instruments in sight. If there is diarrhœa, or if there is any disturbance of the general system, trivial, perhaps, at other time, be still more careful. After two or three days repeat the dose; if there is no reaction increase by one milligramme every second or third day, or even at longer intervals, as the case may require; and so on, being, of course, guided by the revelations of the microscope. Daily examination of the sputum is a *sine qua non* as a guide.

The cases should be selected and under control either in an institution or, in private practice, with a trained nurse at hand. The pulse, respiration, and temperature should be taken frequently and recorded, and the cases seen by the physician at least twice a day. Confinement to the bed does not seem necessary, but quiet should certainly be enjoined in the earlier period of treatment. The usual supporting diet should be continued, and the functions of the heart and kidneys looked after as well as the lungs. It is said that heart-failure has occurred after the administration of the remedy, that the lungs have become œdematous, and the urine bloody in some cases. Several laryngotomies have been done here recently and have successfully bridged over that dangerous period of reaction during which the tuberculous tissue is attacked and becomes swollen, preliminary to being thrown off. Cases with extensive destruction of lung tissue and much prostrated, with our present knowledge of the remedy, are better without this treatment, though much must depend upon the wisdom and discrimination of the physician in gauging the vital resistance.

The reaction, which includes all the phenomena of the twenty-four hours following the elevation in temperature, begins from four to six or even twelve hours after the injection. It does not always occur even when bacilli have been found, and again it does occur and sometimes violently in suspected cases in which no bacilli have been discovered; but time and further investigation must clear up many things that now obscure the beginning. What has already been discovered is wonderful enough. To see a bedridden lupus patient after a few short weeks of treatment walk is astonishing.

The fever ranges from one to five degrees above the normal, and lasts several hours, just as occurs in the usual daily exacerbation in tuberculosis, accentuated perhaps. Query: Is it wise to disturb a dormant tuberculosis by treatment? At present I would say "Let well enough alone." If at any time bacilli show themselves, and there is fever, treatment would appear to be proper. But as all the early symptoms are apt to be uglier in the beginning, cases that appear to have been made worse may after a time be greatly improved by carefully pursuing the treatment.

It would seem quite possible—even probable, that cavities are formed by the diseased tissue being thrown off through the action of the lymph, and that a good cicatrix under ordinary circumstances would result.

"Lymphomania" rages in Berlin; it affects many of the laity and nearly all the medical men, only Drs. Koch and Libbertz enjoying an immunity, so far as can be learned. What is the lymph? It has been suggested that it is a substance resulting from the destruction of the bacillus tuberculosis, held in glycerin and colored by cyanide of gold. It is stated that the German Government will soon control the fluid, or the distribution thereof.

The following seems to be a good method of preparing it for use, especially where a number of patients are undergoing treatment at the same time: Procure a Pravaz hypodermic syringe, which should hold just one cubic centimetre, also two 10-cubic centimetre graduates. Place one cubic centimetre of the lymph (22 drops) in one of the graduates, and add sterilized or carbolized water (½ per cent. solution) to ten cubic centimetres; then of this solution put one cubic centimetre in the other graduate, and add sterilized water or carbolized water to make 10 cubic centimetres. We now have a one-per-cent. solution. One-tenth of the Pravaz syringeful of this solution (the piston is divided into tenths) represents just one milligramme of the original

fluid—the usual dose. The diluted solutions should be boiled each day, *i. e.*, just brought to the boiling-point. This seems a very simple matter, but much confusion and danger arise from careless manipulation. In every minim of the lymph there are about sixty-four doses.

Dr. Koch surely deserves all the honors that are heaped upon him. The remedy stands preëminently as one of the greatest discoveries of the age. Verily, "we of the present stand as heirs of all ages in the foremost files of time."

BERLIN, December 14, 1890.

CRANIECTOMY FOR MICROCEPHALUS.

To the Editor of THE MEDICAL NEWS,

SIR: In the issue of your journal of November 29, 1890, Professor W. W. Keen reported a case of craniectomy for microcephalus, the third on record, and mentions in detail the two operations done by Lannelongue, of Paris, on May 9th and June 20th of this year.[1]

Dr. Keen naturally supposes his the first operation of the kind done in America, no other being reported; but I desire now to put on record the following case upon which I operated on November 8, 1890, some days before Dr. Keen.

The history of my case is as follows: Albert Ginter, white, aged three years, one of twins, born at term (the other child being stillborn), the youngest child of healthy parents. He has two brothers and two sisters, all well and strong, and without hereditary tendency to insanity or other troubles. The child has never walked nor even attempted to crawl, and cannot raise the body from a horizontal to a sitting position nor remain sitting without support. He has an ugly temper, crying incessantly without apparent cause and tossing his head from side to side, with the arms and legs in constant motion. The child never sleeps for a longer period than two hours. He cannot speak, but recognizes familiar faces, being afraid of strangers. There are constant salivation and an abnormal appetite, the child eating almost anything given it. There is no muscular paralysis, although the head is carried somewhat toward the right side and the right extremities are used in preference to the left. Weight, 28 pounds; height, 33 inches. His general health is good, he is well-nourished, and has had no serious illness. Hearing good. As to his vision, my friend, Dr. Hiram Woods, reports: "I find the following condition of things: Normal external appearances, pupils of medium size, readily responding to daylight and to reflected gas-light. The media of the eyes are perfectly clear, the fundus normal, the optic papilla showing a physiological central excavation. Each eye is hypermetropic in shape."

Head measurements: from occipital protuberance to glabella, 8½ inches; from one external meatus to the other, 9 inches; circumference of the head, 18 inches.

I carefully considered the case, and secured the consent of the parents to operate, having offered them the possibility of some improvement. On November 8, 1890, an incision three inches in length was made through the scalp parallel to, and one-fourth of an inch from, the sagittal suture, beginning at the occipital bone.

To expose the skull better, a transverse incision was then made, and the flaps pinned back. The skull being symmetrical, I chose the right side of the middle line for operation, because the muscles of the left side of the body were less used. The first button of bone was removed from a point one-half inch to the right of the sagittal suture and one-fourth inch anterior to the occipital bone. A second button of bone was removed two inches from the first, and at the same distance from the sagittal suture. The intervening bone was removed by rongeur forceps. The opening in the skull when finished measured two and one-half inches long by one inch wide. The dura was normal. Bleeding was arrested, and the flaps were brought in apposition by interrupted silk sutures. The head was dressed and child put to bed. On the fifth day the dressing was removed and the stitches were taken out. The wound had healed by first intention. The child had at no time a rise in temperature.

On December 6th the child presented the following condition: Temper better, sleeps well, and cries less. Takes interest in things around him. When laid upon his back will raise his body on his elbows. Tries to pull up with his hands. Sits in a baby's chair at the table, which he never did before. Has learned to say "papa." When told to play "peep-a-boo," carries his hand to his eyes. When asked for any member of the family, looks around the room until he sees them.

There is evidently some improvement in his mental condition. Time only can determine the extent. Perhaps a future operation on the other side of the skull may be done if it is considered necessary.

SULPHATE OF MAGNESIUM IN THE TREATMENT OF PERITONITIS.

A Bit of Ancient History.

To the Editor of THE MEDICAL NEWS,

SIR: Within the past ten years quite a change has taken place in the treatment of peritonitis, especially with reference to peritonitis arising from surgical operations within the abdominal cavity.

Previous to this present decade opium, blisters and leeches were the mainstays in the treatment of peritonitis, regardless of its cause. But when antiseptic surgery made it justifiable to open the abdominal cavity, and therein determine the origin of diseases that had previously been obscure, a new light was shed upon the whole subject, and from it a new version of many of the affections of this portion of the body has arisen to take the place of much that was unsatisfactory and obscure in former times.

One of the salient features of this new version is the use of sulphate of magnesium in the treatment of peritonitis that may be present either before or after the opening of the abdominal cavity. The impression among most medical men is that Tait originated this method of treatment, and that to him and to his followers who had the pluck to deviate from the beaten track of "splinting the bowels" with opium, belongs the credit of this improved method of treatment. That the method is a decided improvement upon the opium plan in cases

of traumatic peritonitis, whether of external or internal origin, no one who has ever tried it will doubt, and to Tait and his followers much credit is due for their persistent and frequently vehement advocacy of it. But the point is that the method did not originate with them. It was used in the beginning of this century by John Abernethy in exactly such cases as are now deemed best fitted for it, and is probably of much older usage, for it is mentioned by Abernethy as if it were a customary procedure. In *Surgical Observations*, by John Abernethy, 5th edition, London, 1820, p. 5, is cited a case of adherent omental hernia that was operated upon. "The operation was followed by general disorder of the system, manifested by a full, strong pulse, furred tongue, great anxiety, restlessness. . . . The stomach was particularly affected, being distended, uneasy on compression. . . . In the course of the day he took an ounce of the salts (Epsom)." Calomel, senna, colocynth, and aloes were afterward administered before satisfactory evacuations of the bowels took place. In commenting upon this and similar cases, Abernethy claims that disorder of the chylopoietic organs was the cause of the trouble. He says, also: "With respect to the treatment of cases of this description it may be right to add, that the primary object should be to produce secretions from the irritable organs. In many instances *opium* will not prevent continual efforts to vomit, yet when by *sulphate of magnesium* or purgatives administered in the form of pill, and clysters, stools are procured, the vomiting ceases, the stomach retains both food and medicine, and general tranquillity of constitution is as suddenly restored."

When we consider the state of medical knowledge as it was in the beginning of this century, this case becomes a remarkable bit of clinical record, showing the skill of a wise physician and surgeon, who pursued right methods without the guidance of physiology and pathology as we have them to-day. It must be remembered that peritonitis as a distinctive disease was then hardly known, Bichat having recognized and proved it as such but a few years before.

John Abernethy was a remarkable man, and was in several ways one of the many who helped make the present medical and surgical advance possible.

CHARLES M. SELTZER, M.D.
608 N. SEVENTEENTH ST., PHILADELPHIA.

"AN EFFICIENT METHOD OF REMOVING FOREIGN BODIES FROM THE NOSE."

To the Editor of THE MEDICAL NEWS,

SIR: While reading the issue of your journal of December 6th, I came across an item which peculiarly interested me; it is headed "An Efficient Method of Removing Foreign Bodies from the Nose," and is credited to an article by Dr. S. J. Taylor, in the *London Lancet* of November 8th. Dr. Taylor says he got his idea from a communication in the *Lancet* of November 3, 1888, the name of the author of which he could not recall. That communication was my own. I sent it to the *Lancet* while living in Würzburg, Germany.

The idea of the principle occurred to me several years ago and I have had repeated occasions to test its efficacy, so I know the method is an excellent one, being both safe and simple. In Vienna I told one or two of the well-known specialists there of the method and they assured me it was entirely new and original. For natural reasons, therefore, I feel desirous of preserving my claim to its authorship. Very truly yours,

CHARLES W. DODD, M.D.
84 W. EIGHTH ST., CINCINNATI, O., Dec 15, 1890

NEWS ITEMS.

Koch's Lymph in Canada.—A small supply of Koch's lymph having been obtained by Professor Roddick, six patients, with presumably extra-pulmonary tuberculosis, are under treatment in the Montreal General Hospital. The first injection was made on December 19th. So far the usual rise of temperature has been observed, and an increase of albumin in a case of kidney disease. In the case of a girl of fifteen years old, with lupus of the face, local changes are manifest after five injections. Full notes of the cases are taken by Dr. James Bell and the hospital staff.

The Reduced Subscription Price of the "Medical News."—The publishers of THE MEDICAL NEWS desire particularly to call the attention of subscribers to the fact that their remittance should be for ***$4.00*** and not for ***$5.00***, and thereby avoid the trouble attending the return of the extra dollar.

A Lifetime Subscriber.—Very rarely is it possible to record the unswerving fidelity of a lifetime between reader and magazine as is shown between Dr. John D. Ross, of Williamsburg, Pa., and the *American Journal of the Medical Sciences* and THE MEDICAL NEWS. In renewing his subscription, Dr. Ross writes that though a continuous subscriber since 1835, he has never missed a number, and gracefully adds a tribute to the punctuality evinced by both the publishers and the post-office.

In Memory of Richard J Levis.—At a meeting of the Faculty of the Philadelphia Polyclinic and College for Graduates in Medicine the following preamble and resolutions were unanimously adopted:

WHEREAS, The Divine Ruler of the universe has seen fit to remove from among us Dr. Richard J. Levis, our friend and colleague; therefore, be it

Resolved, That in the Emeritus Professor of Surgery of the Philadelphia Polyclinic, not only we but the whole medical profession have lost an honored and faithful co-laborer; and the community have cause to mourn a skilful and learned physician, an honest and sympathizing friend.

Resolved, That by his kindness of manner, by the thoughtful interest which he always manifested in the younger members of the profession, by his encouragement, his earnestness, and his example, he endeared himself to all, and that we fitly honor and cherish his memory. We must emulate his zeal, and vie with each other in carrying forward the great work in which he was so ardently engaged.

Resolved, That we tender to his family in this sad hour of affliction our heartfelt sympathy.

Resolved, That these resolutions be handed to the family of our beloved colleague and to the medical journals. THOMAS J. MAYS, M.D., *President*,
S. SOLIS COHEN, M.D., *Secretary*.

Succi the Faster.—For the last forty-five days an Italian by the name of Succi has been fasting in New York in an exhibition hall. During that time he has lost over forty pounds. The newspaper reports state that his physical condition is very good and his mental condition bright and clear. For the purpose of avoiding the pangs of hunger he daily took an elixir made up chiefly of chloroform and cannabis indica, and his physical condition is very much better than was that of Dr. Tanner. He used during his fast large quantities of water and smoked cigars and cigarettes freely.

The Necessity of Quarantine Against Cholera.—Dr. J. H. Rauch, Secretary of the Illinois State Board of Health, predicts that unless proper quarantine regulations are adopted there will be a serious cholera epidemic in this country next spring. He points out that 10,000 people have fallen victims to cholera in Abyssinia within the last six months; that Spain is infected; that cholera is epidemic in India, and that 80,000 people have perished from the disease in Japan and Corea and the adjacent Asiatic provinces of Russia within a short time. He emphasizes the necessity of protection against the scourge on the Pacific coast.

"Cholera," he says, "has thrice followed the same route from Bekor to Alexandrietta and through the Levant before the Suez canal was constructed. This time the epidemic is being aided by the improved methods of transportation and that monument of pestilence, the yearly pilgrimage of Moslems to Mecca. Thousands upon thousands of these filthy, ignorant Mussulmans congregate at Mecca and spread death and disease. They carry infection into Syria, Turkey, Southeastern Austria and the provinces of Northern Africa. Cholera is there now and its spread will soon be augmented by the Mecca crowd."

Edinburgh Medical Missionary Society.—The November number of the *Journal of the Edinburgh Medical Society* celebrates the fiftieth anniversary of its existence. When the Society was formed the idea of associating medicine with missionary effort "was sneered at by many and scouted by all but a few," whereas now no mission is considered properly equipped, or on an efficient working basis, if it has no medical members. About one hundred and forty such physicians, with British diplomas, are to-day in foreign lands, and, including those from the United States and Canada, there cannot be fewer than three hundred medical workers in heathen and Mohammedan countries, of whom probably fifty are women. Women are especially welcome in the neglected zenanas of India and other parts of the Orient.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 9 TO DECEMBER 29, 1890.

By direction of the Secretary of War, MARCUS E. TAYLOR, *Captain and Assistant Surgeon*, is relieved from further duty at Boise Barracks, Idaho, and will proceed, at the expiration of his present sick-leave of absence, to Vancouver Barracks, Washington, and report in person to the commanding officer of that post for duty, reporting also by letter to the commanding general Department of the Columbia.—Par. 17, *S. O. 287, A. G. O., Washington*, December 9, 1890.

By direction of the Secretary of War, CHARLES M. GANDY, *Captain and Assistant Surgeon*, now on leave of absence, will report in person, without delay, to Colonel Eugene A. Carr, Sixth Cavalry, at Rapid City, South Dakota, for duty with troops in the field, reporting also by letter to the commanding general Department of Dakota.—Par. 14, *S. O. 287, A. G. O., Washington*, December 9, 1890.

RAYMOND, THOMAS U., *First Lieutenant and Assistant Surgeon.*—Having been ordered to temporary duty at Vancouver Barracks, Washington, by the commanding general Department of the Columbia, is assigned to duty at that post, and relieved from further duty at Fort Sherman, Idaho.—*S. O. 294, A. G. O., Washington, D. C.*, December 17, 1890.

Par. 17, of Special Orders No. 287, December 9, from this office, relating to MARCUS E. TAYLOR, *Captain and Assistant Surgeon*, is so amended as to direct him to report to the commanding officer Vancouver Barracks, Washington, for duty as Post Surgeon, relieving Bernard D. Irwin, Colonel and Surgeon, of that duty. Rudolph G. Ebert, Captain and Assistant Surgeon, will be relieved from duty at Vancouver Barracks, Washington, upon the arrival of Captain Taylor, and will then proceed to Fort Huachuca, Arizona Territory, and report in person to the commanding officer of that post for duty.—*S. O. 294, A. G. O., Washington, D. C.*, December 17, 1890.

By direction of the Secretary of War, the extension of leave of absence granted STEVENS G. COWDREY, *Major and Surgeon*, in Special Orders, No. 263, November 10, 1890, from this office, is further extended ten days, on account of sickness.—Par. 4, *S. O. 293, A. G. O.*, December 16, 1890.

By direction of the Secretary of War, FRANCIS J. IVES, *Captain and Assistant Surgeon*, now on leave of absence, will proceed to Rapid City, South Dakota, and report in person to Colonel Eugene A. Carr, Sixth Cavalry, for duty with troops in the field, relieving William B. Banister, First Lieutenant and Assistant Surgeon, and reporting also by letter to the commanding general Department of Dakota.—Par. 18, *S. O. 289, A. G. O., Washington, D. C.*, December 11, 1890.

STEPHENSON, WILLIAM, *Captain and Assistant Surgeon.*—Is granted leave of absence for fourteen days, to take effect on or about December 20, 1890.—Par. 18, *S. O. 291, A. G. O., Washington, D. C.*, December 13, 1890.

By direction of the Secretary of War, WALTER REED, *Captain and Assistant Surgeon*, now on duty at Baltimore, Md., will report in person, without delay, to the commanding officer Fort Keogh, Montana, for temporary duty at that station, and by letter to the commanding general Department of Dakota.—*S. O. 291, Headquarters of the Army, A. G. O., Washington*, December 13, 1890.

By direction of the Secretary of War, WILLIAM O. OWEN, JR., *Captain and Assistant Surgeon*, now on leave of absence, will report in person, without delay, to Colonel Eugene A. Carr, Sixth Cavalry, at Rapid City, South Dakota, for duty with troops in the field, and by letter to the commanding general Department of Dakota.—Par. 17, *S. O. 291, A. G. O., Washington, D. C.*, December 13, 1890.

By direction of the Secretary of War, CHARLES SMART, *Major and Surgeon*, is detailed as a delegate to represent the Medical Department of the Army at the annual meeting of the American Public Health Association, to be held at Charleston, S. C., December 16 to 19, 1890. He will proceed to Charleston, accordingly, and, upon the final adjournment of the Association, return to his station in this city.—Par. 2, *S. O. 290, A. G. O., Washington, D. C.*, December 12, 1890.

By direction of the Secretary of War, ROBERT J. GIBSON, *Captain and Assistant Surgeon*, now on leave of absence, will report in person, without delay, to the commanding officer Fort Meade, South Dakota, for duty with the Seventeenth Infantry in the field, reporting by letter to the commanding general Department of Dakota.—Par. 6, *S. O. 297, A. G. O., Washington, D. C.*, December 20, 1890.

By direction of the Secretary of War, the leave of absence granted FREEMAN V. WALKER, *First Lieutenant and Assistant Surgeon*, in S. O. 85, Department of the Platte, November 11, 1890, is extended one month.—Par. 9, *S. O. 298, A. G. O.*, December 22, 1890.

By direction of the Secretary of War, leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Department of Texas, is granted JOHN J. COCHRAN, *Captain and Assistant Surgeon.*—Par. 2, *S. O. 298, A. G. O.*, December 22, 1890.

By direction of the Secretary of War, WILLIAM J. WAKEMAN, *Captain and Assistant Surgeon*, is relieved from further operation of Par. 13, S. O. 254, A. G. O., October 30, 1890, and telegraphic instructions of the 16th instant, from this office, transferring him from Fort Bidwell, California, to Fort Huachuca, Arizona Territory, and he will return from Reno, Nevada, to Fort Bidwell, for further duty at the latter post.—Par. 3, *S. O. 300, A. G. O.*, December 24, 1890.

ORIGINAL LECTURES.

DIGESTION, ASSIMILATION, AND OXIDATION; THEIR NORMAL AND ABNORMAL CONDITIONS IN RELATION TO HEALTH AND DISEASE.

A Series of Clinical Lectures delivered at the New York Post-Graduate Medical School and Hospital.

BY WILLIAM HENRY PORTER, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY.

LECTURE I.

GENTLEMEN: To-day we shall commence to study together the most interesting and common class of maladies which are presented to the practitioner, namely, those commonly known as "Dyspepsias," or functional derangements of the digestive, absorbing, hepatic, and assimilating tract.

First, however, I wish to present to you an illustrative case, brought to my clinic by Dr. N., of Ellensville, N. Y., for examination and advice as to treatment. The patient, Mr. J., aged fifty-seven years, a carpenter by occupation, tells us that until five years ago he considered himself a perfectly sound and healthy man. From that time he has complained of a sense of soreness in the epigastric region. His appetite has been poor, and he has lived upon a light vegetable diet. Food for some time after being taken causes no distress or pain, but in from one to two hours, or more, distress commences, his abdomen becomes tympanitic, often with considerable borborygmi and general discomfort. This discomfort lasts for a varying length of time, until a reverse peristalsis is developed and the gas which has accumulated in the ascending and transverse colon is forced back into the small intestine, and finally to the stomach, and is then belched up. There is then relief until a few hours after the next meal, when the same phenomena are repeated.

The pain and distress led to the supposition that the stomach was primarily at fault, but the symptoms are not due to a gastric condition, but rather to the over-distended colon, which is wedged in under or posterior to the stomach and presses back upon the solar plexus, thus causing intense pain in the epigastric region. As a general rule, when the primary difficulty is located in the stomach, the pain and distress in the epigastric region come on during or immediately after the ingestion of the meal, and are immediately followed by the eructation of gas and the belching up of an acid, watery fluid, or even by nausea and vomiting.

When the difficulty is in the intestines and liver there is no pain or discomfort immediately after eating, but in an hour or more the distress commences and lasts for a number of hours. Pain now in the epigastric region becomes a prominent symptom, so, also, the tympanites, borborygmus, and general distress until after a considerable time, when the gas escapes by either the mouth or the anus, and relief is obtained.

This patient complains also of pronounced constipation, which shows that there is a deficiency in both the quantity and quality of bile which is discharged into the intestine. When the bile is defective in quality but abundant in quantity, it acts as an undue irritant and tends to produce looseness of the bowels, with frequent tarry and painful stools.

By observing these clinical facts we can differentiate between the two conditions of functional derangement in the bile-producing power, namely, those of over-production and under-production—the quality, however, being impaired in both instances.

This patient also suffers from headache, insomnia, vertigo, and general nervous irritability—a well-marked train of symptoms often classed under the vague term "neurasthenia." These symptoms have continued for five years, until now he is considerably emaciated, frequently suffers from night-sweats, and is physically and mentally weak. The tongue, as you can readily see, is heavily coated, pale, soft, and flabby, and its margins are indented by the teeth. These conditions tell us at once that we have imperfect assimilation and impaired nutrition.

The skin has a dirty, muddy appearance, and looks as if it were thickened, and there is discoloration of the conjunctivæ, indications of hepatic derangement.

In such cases the urine is usually scanty, high-colored, superacid, and of high specific gravity, and, as a rule, does not contain albumin, glucose, or casts. If, however, the condition is very prolonged, it may result in the production of albumin and casts, or glucose, or combinations of these. But more frequently we find an abundance of urates, uric acid, or oxalates, usually the former. In many instances the urine is so intensely acid that it remains perfectly clear and free from deposit for days or weeks after it has been discharged. The rule is, that when digestion and assimilation are properly effected, the urine is but faintly acid, and will change to an alkaline reaction within forty-eight or seventy-two hours at the longest.

By observing these clinical phenomena, and by a study of the urine, both as to its chemical composition and microscopic sediments, and the time at which they are formed, we can learn with certainty where the difficulty is located, and also the condition of the digestive and assimilating functions, and the manner in which the liver is doing its work.

One of my theories in relation to nutrition and disease is, that many of the chronic maladies which we meet with late in life have had their origin, not in inherited taints, but rather in false methods of feeding from infancy up to manhood. If we observe Nature

closely, we notice in almost all classes of animals, the herbivora not excluded, that the primary food-stuff is composed very largely of the nitrogenous, or CHNOS, compounds in contra-distinction to the starches, sugars, and fats, or the CHO class. Organic chemistry teaches us that the animal economy cannot take a CHO compound and join free nitrogen to it and form a proteid substance. Consequently, so far as nourishing or building up any of the component parts of the body is concerned, starch, sugar, and fat furnish no nutriment to the system, and in this sense I shall continue to speak of the CHO compounds as being absolutely non-nutritious, and only of service to the body in so far as they yield heat, energy, lubrication, and rotundity of form. That they are more easily oxidized than the nitrogenous compounds I think no one can deny, and in being more easily oxidized they exhaust the oxygenating capacity of the blood and leave it deficient in a supply of oxygen for the complete oxidation of the nitrogenous compounds. These being incompletely oxidized, true nutrition is impaired and the foundation is laid for an innumerable host of ills.

As I have already asserted, these maladies are directly traceable back to infancy. Nature intended that the infant and growing child should be largely supplied with a nitrogenous pabulum, and with just enough sugar and fat to keep it warm, and to supply lubrication, and a moderate amount of rotundity. So soon as the infant can be removed from the breast or bottle, the invariable tendency on the part of the laity is to take the child away from a strongly nitrogenous diet and substitute a food composed largely of the CHO compounds. The reason for this is that "somebody" has said "that this class of food-stuffs is the best." They, at least, know that it tends to make fat babies that will roll one way as well as the other!

The result of this process of false feeding is that vitality is sapped in infancy, and when the individual is attacked by acute disease he rapidly succumbs to its influence. A false appetite is also established for the CHO compounds—an appetite for a stimulating rather than a nutritive class of food-stuffs. The child soon prefers starch, sugar, and fatty foods to the plain nutritive nitrogenous compounds. Soon the demand on the part of the system for this class of CHO stimulants is not fully met by the starch, sugar, and fat, until, finally, the more active C_2H_6O stimulant—alcohol—is called upon to satisfy the demand. This continues until well-defined habits of intemperance are developed, as is most perfectly illustrated in the Scotch and Irish races, fed, as they are, on the oat and potato until the stronger whiskies alone can satisfy the demands of nature.

Next, we come to the period of puberty, when the generative system is to become more fully developed. These changes call for an increased nutritive supply, but owing to the falsely-acquired appetite and somewhat deteriorated vitality, nature is not equal to the demand, the general systemic vitality fails, or the reproductive organs are incompletely developed. A not uncommon practice is the attempt to assist nature by stimulating with wines or other forms of alcohol, which, although they temporarily improve the condition, still further deplete the nutritive vitality and lay the foundation for diseases of the reproductive organs, nervous system, etc. In consequence of this condition, the reproductive functions, physiologically speaking, remain at a low ebb, if they are not altogether lost.

As the child approaches adult age, when the greatest physical and mental capacity should be present, we find that this false appetite and false method of feeding have become deteriorating factors, and when the attempt is made suddenly to accomplish great physical and mental work there is noticeable a great and rapid expenditure of the vital forces, and the system is left in such a lowered condition that it is literally a good pabulum for disease-germs and poisons of all kinds.

It is by this process of false feeding and devitalization, according to my belief, that the foundation is laid for most of the tuberculosis which appears at this period of life. The proper soil is present upon which the tubercle bacillus can thrive and multiply and stimulate a growth of tubercle tissue. For this reason it seems difficult to comprehend how any treatment which can be brought to bear upon the system shall at once, or in a moderately short time, renourish and revitalize the system so that it can resist the inroads of germs or other forms of organic poisons.

If Koch's lymph will at once revitalize or renourish the individual and at once change habits of years' duration, then, and only then, can it unquestionably stamp out tuberculosis! But, as yet, I am not aware of Koch having made any such assertion.

With these few preliminary remarks, let me say that a thorough understanding of the nutritive functions of the body is of the utmost importance, if we wish to attain anything like success, or the ability to cope with the inroads of either acute or chronic diseases.

First, I propose to study with you the fluids that act upon the materials or food-stuffs which are taken into the system for the growth, maintenance, and activity of the animal economy, and for convenience I have tabulated them in the manner shown on page 31.

The composition of the saliva is rather simple as compared with that of many of the other digestive fluids, and contains only one organic ferment, known as ptyalin. Chemically speaking, the saliva is, however, a more or less complex substance, having an alkaline reaction, a specific gravity of 1005, and containing, besides ptyalin, water, and numerous salts, a trace of derived albumin, mucosine, etc.

The functions of the saliva may be stated as mechanical and chemico-physiological. Under the former heading it may be said to lubricate the mouth and assist in mastication of the food. It also acts as a lubricant to the passage of the bolus through the fauces, pharynx, and œsophagus, and on into the stomach. Having reached the stomach, it is, by its alkalinity, an important factor in exciting gastric secretion. This action is produced according to the common law, that alkalies brought in contact with acid-secreting membranes tend to stimulate the flow of acid secretions, while acids brought in contact with acid-secreting membranes tend to decrease the flow of the acid secretion. The reverse of this law is true for the alkaline-secreting membranes. If we wish to develop and retain the most perfect digestion, the food-stuffs should be thoroughly masticated in as dry a state as is compatible with comfort; for by so doing the largest possible amount of alkaline saliva is

excreted, which, as we have already seen, is an important factor in exciting the gastric flow. We must abandon the American fashion of bolting the food and washing it down in solid lumps with some fluid, such as milk, tea, coffee, or alcoholic stimulants. Many of our digestive difficulties commence in this way, by depriving nature of one of her stimuli. This leads also to similar difficulties lower down in the alimentary canal.

Fluid or tissue.	Ferment.	Action.
Saliva.	Ptyalin.	Converts starch into maltose.
Gastric juice.	Pepsin.	Converts proteids into peptones.
	Milk-curdling.	Curdles caseine of milk.
	Lactic acid.	Splits milk sugar into lactic acid.
	Fat-splitting.	Splits fats into glycerin and fatty acid.
Secretion of Brunner's glands.	.....	Liquefies proteids at 98.5° F.
		Converts maltose into glucose.
Pancreatic juice.	Amylopsin.	Converts starch into maltose.
	Trypsin.	Converts proteids into peptones.
	Steapsin.	Splits fat into glycerin and fatty acid.
	Milk-curdling.	Curdles caseine of milk.
	Emulsive.(?)	Emulsifies fat.
Intestinal juice.	Diastatic.	Converts maltose into glucose.
	Proteolytic.	Changes fibrin into peptone.(?)
	Invertin.	Changes cane sugar into glucose.
	Milk-curdl'g(?)	Curdles caseine of milk.(?)
Bile and bile acids.	.....	Emulsifies neutral fats.
		Converts starch into sugar.
		Converts glycogen into sugar.
		Excites contractions of muscular coat.
		Stimulates muscles of the villi.
		Excites vital activity of intestinal epithelium.
		Moistens intestinal wall.
		Lubricates the colon.
		Prevents decomposition; is antiseptic.
Hepatic function.	Glycogenic.	Changes glucose into glycogen.
	Bile-secreting.	For use in digestion.
	Bile-excreting.	To eliminate poisons and drugs.
	Peptone-destroying.	Converts peptones into serum-albumin, and globules.
	Ptomaïne-destroying.	Converts poisonous ptomaïnes into inert ptomaïnes.
	Germ-destroying.	
Blood.	Diastatic fibrin forming.	
	Fibrin-forming ferments.	
Chyle. Liver.(?) Milk. Most tissue.	Diastatic ferments.	
Muscle.	Peptone-forming ferments.	

The chemico-physiological activity of the saliva is located in the ptyalin, which is an organic nitrogenous ferment, having for its function the hydration of starch, or the conversion of starch into maltose, conveying it, as it were, one step forward in the chemico physiological process. This action is effected in only an alkaline solution, or in an acid medium the percentage acidity of which has not exceeded ten per cent. In this respect it is essential that a large quantity of the alkaline saliva should be carried into the stomach, for it not only helps to excite the flow of gastric juice, but it also keeps down the acidity of the fluids contained in the stomach, thus giving the ptyalin a longer time in which to act upon the starches, and so decreases the amount of work that otherwise must be accomplished in the intestines or left undone.

My advice to patients is never to drink liquids of any kind while eating, but to take the food as dry as possible. This, of necessity, requires more prolonged mastication to excite sufficient saliva for the easy passage of the bolus to the stomach. By following this rule the largest possible amount of alkaline saliva is carried into stomach with each meal. With this method of eating, the food in the stomach is necessarily in too solid a state for the most perfect gastric digestion, and to obviate this difficulty completely fluids should be freely taken before or after the meal. This causes the particles of food in the stomach to be widely separated, and thus to present the largest possible surface to be attacked by the gastric digestive fluids, and at the same time the sum total of its alkalinity has not been reduced. The best fluid to be taken after a meal is coffee, made not very strong, and drunk without milk or sugar. The active principle of the coffee—caffeine, $C_8H_{12}N_4O_3$—is a safe stimulant to use, being a nitrogenous substance that can be utilized as a food, which is not the case with the purely CHO compounds.

Having reached the stomach under the most favorable circumstances, we find, by reference to our table, four ferments besides the hydrochloric acid to act upon the food-stuffs before they are passed on to the intestines. These are the milk-curdling, peptic, lactic-acid forming, and the fat-splitting ferments. The presence of the first and second is unquestioned and of the most importance. The third is quite generally accepted, while the fourth is somewhat in doubt.

For convenience of study our food-stuffs may be separated into two common classes: first, the nutritious, albuminous, nitrogenous, or CHNOS compounds, and, second, the non-nutritious starches, sugars, and fats, or the CHO compounds.

As milk is largely used, both as an ordinary article of diet and as a special diet for the sick, I will refer, first, to changes produced in it before its nitrogenous compound, the caseine, is ready to be attacked by the true digestive processes. The milk, as ordinarily taken, is in a fluid state. Its caseine must be precipitated before the hydrochloric acid and pepsin can act upon it. In the secretions of the stomach there are two substances capable of precipitating caseine—hydrochloric acid and a special organic ferment known as the milk curdling ferment. If the caseine is precipitated by the hydrochloric acid of the stomach, it will be solidified in hard, tough, and leathery lumps, but when precipitated by the milk-curdling ferment it is thrown down in fine, feathery flakes, presenting a large surface and easily permeated and digested by the pepsin.

It is a well-known fact that when the milk or any food-stuff is taken into the stomach cold, it tends to excite a free flow of hydrochloric acid and decreases the

milk-curdling ferment; the reverse takes place when the milk or any food-stuff is taken warm. Milk taken after a hearty meal comes in contact with an abundance of hydrochloric acid, and is apt to solidify in hard, tough lumps, and to impair digestion. Therefore, to have the milk placed under the most favorable circumstances for digestion, it should not be taken cold, or with, or after, a full meal, but should be taken quite warm, or even hot, and alone. The addition of lime-water also favors precipitation in this fine, feathery form. I am, however, in the habit of using small and repeated doses of fel bovis inspissatum, which seems to stimulate a flow of the milk-curdling ferment. By observing these rules and administering the fel bovis, I have yet to see a stomach that cannot easily be made to prepare the milk thoroughly for the action of the hydrochloric acid and pepsin.

The next step in the digestive process in the stomach is the action of the hydrochloric acid. This acid, which is the true acid secretion of the gastric juice, attacks all forms of albuminous or nitrogenous compounds, vegetable as well as animal, and changes them from a native or derived state into a uniform acid-albumin, commonly called syntonin. The reason for this change is the fact that the pepsin can attack an acid-albumin only, and for its perfect action requires an acid medium. The pepsin produces a peculiar and gradual gelatinization, by which the semi-solid syntonin is transformed, first, into a propeptone, then into albumoses, and, finally, into a liquid and easily-diffusible peptone. An important fact to be remembered in connection with the peptonizing process in the stomach is, that the peptic action is a slow and comparatively weak process, and, as a result, only a small portion of the albumin is completely transformed in the stomach into a diffusible peptone. The major part passes untransformed into the intestine, where it is changed into an alkaline albumin, to be attacked by the more vigorous and erosive tryptic ferments of the pancreatic and intestinal secretions, and converted into a peptone.

The starches, sugars, and fats, practically speaking, are unaffected in the stomach, but the nitrogenous envelope surrounding the starch granule or oil globule may be digested away, thus setting free the granulose and oil. This has been called "the starch-hydrating and fat-freeing action of the stomach."

The lactic-acid ferment, under favorable circumstances, is said to attack the saccharine elements, causing fermentation and the production of lactic acid. This fermentative process can occur only when there is a decreased flow or absence of the acid and peptic qualities of the gastric juice. This process of lactic-acid fermentation is now supposed to be the explanation of the presence of lactic acid in the gastric secretion, and of the former belief that it was the normal acid of the gastric juice. This formation of lactic acid is believed by some to be the origin of the superabundance of acid in the stomach in so-called acid dyspepsia, and that overacidity is not due to an abnormally large flow of the normal hydrochloric acid. In a few instances this is unquestionably true, but in by far the largest number of cases there is a hypersecretion or hyperacidity of the gastric juice, which is the true cause of acid dyspepsia. In acid dyspepsia which has resulted from lactic-acid fermentation, the eructation of acid fluid or gas does not come on immediately after taking the food, but is developed some time later, and is intensified by taking saccharine food. When due to hypersecretion of the normal acid the symptoms come on immediately, and in the absence of saccharine foods.

In regard to the fat-splitting ferment but little is known. The theory advanced, however, is that this ferment is generated by the stomach and acts upon a limited amount of fat, splitting it into its component parts—glycerin and fatty acids.

Crediting the stomach with the largest possible amount of work, we find that it has comparatively little to accomplish. It practically has no action upon the starch, sugars, or fats, and transforms only a portion of the nitrogenous elements into a complete peptone. Therefore, I have been led by these physiological studies, and by observation in a large number of clinical and pathological examinations, to believe that there are very few stomachs which are not fully capable of performing the necessary amount of work; that in the majority of instances of so-called dyspeptics the stomach is not at fault, and that one great reason why dyspeptics do not get well, is because treatment is entirely directed toward the stomach and away from the true seat of the malady.

INFLAMMATION IN AND ABOUT THE HEAD OF THE COLON.[1]

BY L. S. McMURTRY, M.D.,
GYNECOLOGIST TO STS. MARY AND ELIZABETH HOSPITAL; FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS, ETC.; LOUISVILLE, KY.

INCIDENT to the remarkable advance in peritoneal surgery during recent times is an entire recasting of the pathology and treatment of deep-seated inflammations of the right iliac fossa. Our increase of knowledge regarding the origin and nature of these conditions has come from the ready access to the peritoneal contents, and particularly from the disclosures of that unequalled diagnostic resource, the exploratory incision.

The teachings in most systematic treatises on surgery and practical medicine upon inflammation and its results in and about the caput coli are not only practically worthless, but positively misleading. This is true not only in regard to pathology and treatment, but even in regard to the anatomy and relations of the cæcum and its appendix. The only literature of practical value upon this subject is scattered through the journals of the past three years, and, with the exception of the able papers of Sands, Hoffman, McBurney, and Weir, consists of a few reported cases. The frequency of the disease, the importance of its early recognition, together with my own recent experiences in its operative

[1] Read before the Southern Surgical and Gynecological Association, November 12, 1890.

treatment, have induced me to present this paper upon the subject.

Scarcely a decade has elapsed since so experienced a surgeon as the late Dr. H. B. Sands, of New York, announced, in a paper on this subject, that in the course of twenty years he had seen twenty-nine cases of appendicitis. During the past year many surgeons have met with a dozen or more cases, and the ability to recognize the disease and the resort to appropriate operative treatment are fast increasing. This great advance in our knowledge and resources is the direct result of the labors of American physicians and surgeons, the most notable contributions being from Sands, Weir, Fitz, Pepper, Morton, Hoffman, McBurney, Dennis, and Stimson.

It is now well known that inflammatory changes of the vermiform appendix are, in almost every case, the origin of the inflammatory diseases about the caput coli. Inflammation of the cæcum is very rare, yet the testimony of surgeons and pathologists is abundant that in a certain proportion of cases cæcitis, with perforation, occurs without involvement of the appendix. Regnier, in 1886, operated by abdominal section on a case presenting symptoms of intestinal obstruction with peritonitis. At the autopsy cæcitis, with perforation, was discovered.[1] Other cases have been reported, and verified by post-mortem examination. In 1888, I operated on a case of perforative cæcitis, and sutured two perforations in the cæcum. The patient recovered, and was present in the Section of Surgery of the American Medical Association in May, 1888. A full report of the operation can be found in the *Journal of the American Medical Association*, July 7, 1888. In this case I carefully examined the appendix, and found that it presented no indications of disease. Compared, however, with appendicitis, cæcitis is a very rare condition. McBurney estimates the relative frequency of cases of cæcitis and appendicitis as one to one hundred. I should place the proportion as much less, and believe it would be nearer the mark to say one to two hundred.

Fæcal impaction has been mentioned by surgical writers as a cause of inflammation about the head of the colon. Pain over the cæcum, with a fæcal mass perceptible on pressure, often occurs, but is rarely, if ever, associated with peritonitis. A few weeks since I saw a case with Dr. H. H. Grant, of Louisville, in which there was localized peritonitis in the right iliac fossa, with a well-defined, firm tumor. Abdominal section was done, and, instead of appendicitis, we found the disease to be cancer of the caput coli. Irrigation and drainage rescued the patient from the immediate danger of active peritonitis. The patient was a woman of middle age, and the engrafted peritonitis presented the symptoms of an acute condition. Malignant disease of the cæcum has not, so far as I am aware, been mentioned by writers upon this subject as a probable condition in the diagnosis of deep-seated inflammations of the right iliac fossa.

Practically speaking, however, localized peritonitis about the head of the colon is, with very rare exceptions, caused by inflammation of the vermiform appendix. Unlimited confusion in the study of this subject has been caused by the use of the terms peri-typhlitis and para-typhlitis, and intra-peritoneal and extra-peritoneal abscess. It has been taught that peri-cæcal inflammation may be of two distinct anatomical characters—that the cellular tissue around the cæcum may be inflamed and abscess result, without involving the peritoneum, and that in such cases the surgical treatment should consist in a dissection by which the peritoneum is pushed to one side and the abscess opened and evacuated. This is altogether misleading. In not a single case in which I have operated or seen others operate, was there a doubt that the pus was within the peritoneal envelope. This is the unqualified testimony of Weir, McBurney, and others, who have studied the subject from the standpoint of practical experience. Weir has shown, in an analysis of one hundred autopsies, that in not a single instance did the abscess originate in the extra-peritoneal tissue, and that in only four was pus found in the tissues. When an operation is done in the early or middle stage of the disease, there will be no doubt upon this point; but late operations, and operations in neglected cases, may show that pus has broken through the lateral or posterior layers of the peritoneum and forced itself along the intra-muscular spaces. Even this condition is very rare, and the greater part of the abscess is really intra-peritoneal. Moreover, Treves has demonstrated, by an elaborate series of dissections, that the cæcum and appendix are wholly within the peritoneal cavity.

When inflammation of the appendix and the attendant peritonitis occur, adhesions glue together the adjacent coils of intestine, and shut off the general peritoneal cavity. The same conservative process occurs in pyosalpinx. In each instance the diseased structures are intra-peritoneal, and in each instance the outlet may follow diverse directions, if left to itself. The operation for either condition is a veritable abdominal section. These anatomical and pathological facts have now been established beyond question, and the time has come to cease talking and writing about the cellular tissue covering the posterior surface of the cæcum, of cellulitis, of extra-peritoneal abscess, of para-typhlitis, and of operations in which uninflamed peritoneum is pushed away from the iliac fossa and

[1] Traitement Chirurgicale de la Peritonite, 1886, p. 57.

the posterior cellular space is opened and evacuated. These things do not exist or occur, and should be dismissed from future discussions of this subject.

Inflammation of the appendix varies in degree, from a simple catarrhal inflammation with infiltration of the submucous tissues, to perforation and complete gangrene of the organ. The course and progress of the inflammation may be acute, subacute, or chronic, giving rise to a clinical history characterized as fulminant, explosive, recurrent, mild, etc. The lesions likewise vary, and there may be found slight obstruction from thickening of the mucosa, stricture of one or more portions of the lumen of the appendix, adhesions to the cæcum and contiguous organs, a distended cyst holding an ounce or more of pus, or perforation and separation from the cæcum by sloughing.

The starting-point of the inflammatory process seems to be in the mucosa, but the exact nature and cause of the process are as yet undetermined. The appendix normally varies in size and conformation, and in many instances lesions have been attributed to congenital defects due to errors of development. It also varies much in length, as well as in its approximation to the external surface of the cæcum. Fæcal concretions and foreign bodies have been regarded as the causes of the inflammations, but the experience of Stimson and some others is opposed to such an explanation of the morbid process. Of twenty-one cases reported by Stimson, in only one was a fæcal concretion or a foreign body of sufficient size to have caused the inflammation found. In all, however, there was marked inflammation of the mucosa, which in some instances had destroyed its structure. Total or partial obliteration of the lumen was found in three cases, and in one the stricture was double. It is my belief that fæcal concretions, catarrhal inflammation, obstruction, and retention are the initial steps in inflammatory lesions of the appendix, to which the peritonitis known as that of contiguity is added.

The appendix is often found buried in and attached to a mass of inflammatory exudate which has become firm bands of false membrane. The signs of previous inflammatory attacks and chronic inflammation corresponding to the evolution of symptoms are often found. Ulceration and perforation, associated with suppurative peritonitis, are common lesions of the appendix. The lesions and their results are very similar to those of purulent salpingitis. The adjacent coils of intestine are agglutinated, shutting off the general abdominal cavity, and thus an abscess boundary is formed. The burrowing pus may pursue various and circuitous routes to an outlet. It may break down adhesions, extend its area, and excite a suppurative peritonitis involving the entire abdominal and pelvic cavities. It may perforate the parietal peritoneum and burrow along the cellular interspaces of the abdominal muscles. It may discharge through the loin, or through the scrotum, or perforate into the rectum, bladder, or pleural cavity. The abscess is always intra-peritoneal in its origin and seat, though it may discharge its contents at remote points.

The diagnosis of appendicitis, with any estimate of the extent and severity of the lesions, is not only exceedingly difficult, but, as a rule, impossible. In many autopsies evidences of appendicitis without extensive peritoneal involvement, and terminating in resolution, are observed. That such lesions are often mistaken for simple intestinal disturbances, or pass unnoticed, there can be no doubt. In many instances the attack is much more pronounced. It may be quite severe and characterized by pain, tenderness, swelling, and febrile action, and yet terminate in resolution and recovery. But the inflammation is very prone to recur and to terminate eventually in peritonitis and abscess. Dr. McBurney describes the case of a young lady, in which twelve attacks occurred in the course of little more than a year. She was relieved by removal of the appendix, which was swollen and inflamed.

In cases in which perforation most commonly occurs the history is different. The attack is sudden and the symptoms fulminant. This form of appendicitis is well illustrated by the following case upon which I operated in July last. I give the clinical history in the words of Dr. J. B. Kinnaird, of Lancaster, Ky., who attended the patient from the inception of the attack, and was present when I operated.

"Alice K., six years old, was attacked by pain in the abdomen, July 6, 1890. When I called she had had several small stools, and being informed by her mother that the child had been eating gooseberries, I considered it a case of cholera morbus, and prescribed a saline cathartic. The bowels acted, but on the following day she was not relieved, and continued to complain of pain. In the afternoon of this day she had a severe paroxysm of pain, referred to the ileo-cæcal region. On the morning of July 8th she seemed better. She had taken a small Dover's powder the night before and had rested well. In the afternoon of this day I found her lying on the lounge playing with her brother. She was bright and cheerful, but her temperature was 101° and pulse 140. On the following morning the abdomen was painful, especially about the ileo-cæcal region. I prescribed small doses of Dover's powder, and applied moist, warm applications. In the afternoon of this day there was tympanites, the legs were drawn up, features pinched, pulse rapid, temperature 103°, and vomiting occurred and continued. Dr. McMurtry was summoned from Louisville, and arrived during the night. Abdominal section was done on the following morning, July 10th, the fourth day of the illness."

On opening the abdomen by an incision along the outer border of the rectus muscle, several ounces of foul pus escaped. The intestines were matted together, but were readily separated, and the appendix found. I tied it off with silk and removed it. The abscess cavity was thoroughly irrigated and a rubber drainage-tube inserted. The little patient's pulse was rapid and feeble when she was put on the table. It did not improve after the operation, and she died ten hours subsequently.[1] The appendix was perforated in two places and contained a fæcal concretion.

This child was apparently in perfect health four days before her death, and the lesions shown in the specimen presumably occurred in that time. Her features were pinched, her belly tympanitic, pulse 150, temperature 103½°, tongue dry and furred, and condition extreme when the operation was done. She had general peritonitis.

This case is a powerful argument in favor of early operation when we view the lesions presented in the specimen.

A tumor of varying size can usually be made out in the early stage of appendicitis, but often this sign is not distinct until the patient is relaxed by an anæsthetic. The tumor is formed by infiltration and effusion about the cæcum, perhaps by pus, or by agglutination of the intestines.

Tympanites is a very inconstant symptom. Its presence or absence, or its degree, are of little value in determining the severity of the inflammation or extent of the lesions. Pain is a constant symptom, but often extends through the abdomen. Usually, however, a painful point can be detected on firm pressure immediately over the caput coli.

The patient assumes the dorsal decubitus, and, as a rule, draws up the right leg and retains it so.

The aspirator, as an exploring instrument, is unreliable and dangerous in inflammations deep in the right iliac fossa.

Rectal examination in the early stages of this disease is without value in the diagnosis, and is rarely of aid in any stage.

Rigidity of the abdominal muscles, more marked on the right side, is almost invariably present, and constitutes a valuable diagnostic sign.

A rapid pulse, varying degrees of fever, a chill, and vomiting are often present, but are so frequently absent as to be in themselves of no special significance.

When suppuration has occurred, rigors, sweats, and a dry, furred tongue are observed.

Perforation may occur without any special aggravation of the symptoms. In certain mild cases perforation or rupture may be accompanied by sudden aggravation of the symptoms; yet in other instances perforation has been found without any increase in the severity of the symptoms. From this it is apparent that no decision as to the propriety of operative interference can be based upon a diagnosis of perforation.

In order to illustrate the varying symptoms and sometimes protracted course presented by appendicitis, I will record here another case upon which I operated in September, 1890:

W. D. S., male, aged twenty-six years, was taken ill in June. He consulted a physician and received treatment. Diarrhœa came on, and he was confined to bed with pain in the bowels and fever, which were attributed to malaria. In July he travelled a short distance by rail to the Springs. Another physician then treated him for rectal disease by means of local applications. His troubles persisted and confined him to bed during the entire month of August. On September 1st I visited him at the Springs. He was emaciated, had frequent rigors, profuse sweats every night, a pulse over 100, and constantly elevated temperature. He was taking three grains of morphine daily. Pain and an oblong tumor in the right iliac fossa were present.

I performed abdominal section on September 6th, the incision being along the external border of the right rectus muscle. In opening the peritoneum, which was thickened and attached to the adjacent tissues, fully six ounces of putrid pus escaped. While irrigating the abscess cavity the sloughing appendix was washed out with the contents of the abscess. A double rubber drainage-tube was inserted, and frequent irrigation instituted. This was continued until the discharge ceased, which was at the end of nine days, when the tubes were removed. The patient's improvement was immediate and his recovery was complete.

This case, while illustrating remarkable tolerance and resistance of the peritoneum, is a distinct plea for operative interference.

Turning now to the treatment of inflammation of the appendix, the first and most important observation I would make, is that at the beginning of the attack we have no means whatever to determine whether the disease will pursue the course of the first case or that of the last case which I have reported in this paper. That is, we cannot foresee whether the patient will have general peritonitis, and be beyond rescue in three days, or whether, after a long illness with suppuration and destruction of the appendix, he can be restored to health. We cannot from any known symptoms foresee whether a case will be a simple catarrhal inflammation terminating in resolution, or a recurrent attack, or whether it will become an unprotected perforation, followed by immediate infection of the general peritoneum, and death. A recognition of this fact is of the utmost importance in deciding upon a plan of treatment. It gives to the so-called conservative plan, known as expectancy, an unseen peril which

[1] Dr. McMurtry exhibited the appendix to the members of the Association.

is generally wholly disregarded in the treatment of this condition.

So far as the use of palliative remedies is concerned, the treatment is limited to a few simple measures. A saline purgative, aided by an enema, in the early stage of the disease, will tend to reduce congestion, remove fæcal accumulations, and prepare for surgical interference. Opium obscures symptoms, arrests elimination, and is positively contra-indicated.

In view of the insidious nature of the disease, of its rapid progress, of its frequent recurrence, and of the early period in which apparently mild cases may assume a fatal character, operative treatment cannot justly be delayed. In a certain number of cases termination by resolution takes place in three or four days. When the symptoms are marked and the inflammation of high grade, lives will be lost by waiting even three days for spontaneous recovery. In the larger proportion of cases recovery will not occur by resolution, and they may at any moment assume a fatal character. In these cases abdominal section and removal of the appendix should be done as soon as the character of the disease is recognized. In connection with this, it is important to remember that the dangers of a recurrent attack are greater than those of a primary one.

The mortality of appendicitis, as heretofore recorded, is extremely severe. Fitz, who has recorded the largest number of cases, says: "Seventy-four per cent. recovered and twenty-six per cent. died. About one-half of these were treated medically and the other half surgically." This, of course, indicated that those treated surgically were operated upon late in the disease, which, we all know, means that the patients were practically moribund. The late operation has the enormous mortality of fifty per cent.

Every case of appendicitis passes through the great danger of an unprotected perforation before reaching the comparatively safe condition of abscess. The decision to operate should be determined more by the grade of the inflammation than by the time it has existed. When a diagnosis has been made, and three days have elapsed without diminished pulse-rate and temperature, operation should be done.

Finally, I would submit the following conclusions:

1. Inflammation about the caput coli is, as a rule, appendicitis.

2. A certain proportion of cases will recover spontaneously by resolution. With these, recurrence of the disease is common.

3. In the larger proportion of cases the disease endangers life, and may at any moment assume a practically hopeless condition.

4. Operation involves less danger than delay, and should be resorted to in all cases in which a high grade of inflammation is persistent.

5. The essentials of the operative technique are brief anæsthesia, quick and thorough work, removal of the appendix, irrigation, and drainage. The lateral incision is preferable to the median.

DISCUSSION.

In discussing this paper, Dr. Joseph Price, of Philadelphia, agreed with the author upon the necessity of operating early in cases of appendicitis, and said that prompt evacuation of pus, wherever situated, is the only proper method of treatment. He then reported some illustrative cases which had occurred in his own practice.

Dr. Bedford Brown, of Alexander, Va., referred to a remarkable case of typhlitis that came under his care during the late war. The patient was a Confederate soldier, and was brought into the speaker's field-hospital, Richmond, in the summer of 1862. It was supposed that he had an abscess on the inner side of the knee-joint. He was greatly emaciated and had fever and night-sweats. The patient called attention to a swelling in the right iliac region, which was accompanied with pain and tenderness. Dr. Brown opened the abscess near the knee freely, and evacuated half a pint of pus. Mixed with the pus were grains of green corn, tomato seeds, small chicken bones, and blackberry seeds. A cæcal abscess had evidently formed, and the pus had escaped under Poupart's ligament through the femoral ring, followed in the course of the sartorius muscle, and finally accumulated on the inner side of the knee-joint. The fistulous opening was probed with a soft male catheter, and found to extend up to Poupart's ligament. Finally it closed, and the man recovered completely and resumed his duties as a soldier.

Dr. Brown's subsequent experience with typhlitis comprised only six or seven cases. Of these, all recovered under general treatment but one, and that one was finally operated on and died shortly after.

Dr. G. Frank Lydston, of Chicago, referred to the very great progress which has been made in recent years in the diagnosis and treatment of this class of affections. Dr. McMurtry had well said that inflammation of the cellular tissue is not the cause of the inflammatory affections which occur about the head of the colon. It might be said that the cellulitis which occurs in this region bears the same relation to the pathological foundation of the process that so-called, pelvic cellulitis, bears to pathological conditions affecting the uterine appendages, although a little more importance should be assigned to the part which the cellular tissue plays in the pathological conditions incident to appendicitis. There is no question, he thought, that in many cases inflammation of the extra-peritoneal cellular tissue—*i. e.*, Velpeau's membrane—has much to do with some of the peculiarities of perityphlitic abscesses. This is especially true in retro-cæcal abscess. He also differed from Dr. McMurtry in the opinion that the inflammation and abscess are always intra-peritoneal. Leaving out of consideration those recent anatomical dissections to which allusion was made, there is no question that in some instances the inflammation may agglutinate the

peritoneum about the appendix and perforate into the retro-peritoneal cellular tissue. This, Dr. Lydston thought, is the explanation of the slowness with which some abscesses in this location come to the surface. Instead of the induration being at once manifest, it may be several days or weeks before it can be detected; the abscess, meanwhile, burrows along the planes of cellular tissue in the iliac fossa to the ilio-lumbar region, and may appear at some distance from the head of the colon, or may gradually burrow outward toward the loin and both downward and upward in the direction of the groin until at one or more points it becomes perceptible to the touch. In a considerable experience with the conditions described by Dr. McMurtry, the speaker had observed several cases of this sort, and in one instance in which he operated he was confident that the process was extra-peritoneal and that the abscess had burrowed upward in the direction of the kidney, as well as downward into the iliac fossa.

Another point that must be considered, he said, is that if all these abscesses be regarded as primarily intra-peritoneal, the operator may lose sight of the fact that in some cases he can do what is practically an extra-peritoneal operation, for, as Dr. McMurtry admits, there is a barrier produced by adhesions between the collection of pus and the general abdominal cavity.

Dr. Lydston believed that some cases are due to inflammation which does not begin in the appendix, but in the colon proper; this inflammation may, he thought, extend to the cellular tissue outside of the colon, without there being necessarily any perforation. The same is true in cases in which the inflammation primarily or secondarily affects the appendix.

The question of the relation of foreign bodies to this process is quite definitely settled; the foreign body, however, is not necessarily of extraneous origin. Very frequently, as a consequence of constipation, catarrhal colitis is set up; this extends to the appendix, and there is slight swelling of the appendico-cæcal opening. Mucus collects in the appendix; a small amount of fæcal matter gets into the little tube during straining at stool, but fails to get out again, and forms, in combination with the mucus, a small fæcal stone. Sometimes this fæcal stone is formed in the cæcum, and is forced into the appendix. Oftener, however, it forms in the appendix proper. The concretion may set up inflammation in and about the appendix, or may perforate and in that way cause inflammation and suppuration. Sometimes the fæcal stone escapes into the pus and becomes dissolved. This, the speaker thought, is the explanation of those cases in which perforative ulceration of the appendix is found, and yet no foreign body is discernible in the pus-sac. Dr. Lydston believed that in every case in which perforation occurs there has been a foreign body of some kind.

In general, the causes of perityphlitis may be said to be (1) fæcal impaction in the colon; (2) fæcal stone; (3) extension of catarrhal colitis, with occlusion of the mouth of the appendix; (4) foreign bodies of extraneous origin; (5) traumatism. The latter may be disputed, but the speaker has seen one case in which traumatism seemed to be the cause. Many cases of appendicitis remain catarrhal.

The diagnosis of perityphlitic abscess is not always easy. He recalled one case in which he was ready to operate, the symptoms pointing to the presence of pus, and the fulness of the ileo-cæcal region and tenderness of that point seeming to warrant an operation. Operation was, however, refused, and the patient recovered after the passage of a large amount of fæces. Fitz reports a case of circumscribed peritonitis in the right iliac region diagnosed as appendicitis, which at the autopsy was proven to be abscess of the liver due to catarrhal colitis. In a second case, diagnosed appendicitis, the post-mortem examination disclosed a suppurating subperitoneal gland due to gonorrhœal infection. In a third case salpingitis was mistaken for appendicitis. In a case of his own there was appendicitis with a small abscess, but all of the symptoms which existed prior to the operation have since persisted, and are unquestionably due to spinal irritation.

The mortality-rate reported from operations for perityphlitic abscess should not guide us in the question of operating, as these cases are usually operated on very late. The results of surgical treatment depend a great deal on what is done. For example, the operation may be (1) extra-peritoneal; (2) intra-peritoneal; (3) the appendix may be resected; (4) the operation may be no more formidable than the lancing of an abscess.

A valuable point in diagnosis is the fact that when an abscess forms behind the cæcum and tends to burrow upward toward the kidney, there will be marked irritation of the psoas muscle with flexion of the thigh, crural neuralgia, and great pain on attempting to straighten the limb.

As for aspiration it can only be condemned. If pus has not formed the abscess does not need aspirating, and after it has formed aspiration does no good. It is dangerous and illogical.

Fæcal fistula occurred in one of his cases after operation, the procedure having been delayed too long. The fistula, however, healed within three weeks. The most important point in connection with perityphlitic inflammation is, in his opinion, that many children who are said to have idiopathic peritonitis have had, primarily, inflammation about the appendix. In children the inflammation extends to the sensitive peritoneum so rapidly that a fulminant peritonitis results and destroys the patient's life long before the period when, in the adult, suppuration and a distinct tumor would be observed. The speaker wished to put himself on record as denying the existence of idiopathic peritonitis in children; all the cases are due either to some disease of the bowels, of which appendicitis is one of the most frequent conditions, or to traumatism. As Dr. McMurtry suggests, operation should be the rule in perityphlitic inflammations. It is well to remember, however, that a proper selection of cases is necessary here as elsewhere. Not all cases require operation, but whenever pain, induration, rapid pulse, and high temperature tend to persist the operation should be done; also whenever the induration is marked it should be performed without delay.

DR. JOHN D. S. DAVIS, of Birmingham, Ala., could not agree with the essayist as to the cause of appendicitis. It is sometimes, though in rare instances, the result of concretions, of various kinds, of seeds, etc.

The method of operating by ligating the appendix is a very hazardous procedure indeed, and the method

suggested by Dr. Price is the wisest course to pursue. The appendix should be amputated closely, pushed in, and then closed with Lembert sutures. We often find in this region that the inflammation has continued so long that the serous membrane is destroyed, and we will not have primary adhesion, even when it is closed, serosa to serosa, with Lembert sutures. Therefore, it is the best policy to amputate close to the cæcum, close the mucous coats with a continuous suture, then push the stump in and unite, serosa to serosa, by means of the interrupted suture.

DR. J. MCF. GASTON, of Atlanta, Ga., said that he first called the attention of the profession to appendicitis at the meeting of the American Medical Association in St. Louis. He has written papers on the subject since, but instead of referring to them he would briefly report the case of a physician which came under his observation recently, and which terminated fatally without having time to develop suppuration, but presented the symptoms of collapse, resulting from perforation. At the post-mortem examination the fact that there had been ulceration was verified. There seems to have been a cause which could not be discovered. The patient had been repeatedly eating grapes at his breakfast for some time, but unfortunately the undertaker injected a large quantity of fluid into the abdomen, which rendered it impossible to determine definitely the cause of death. There was evidently an opening at the most dependent portion of the appendix, but this looked as though it had previously existed and had been shut off by a circumscribed inflammation around it, which prevented the development of serious consequences. There was another ulceration or perforation near the attachment of the appendix to the cæcum, and it was evidently through this that the contents of the cæcum had discharged into the peritoneal cavity and led to the collapse.

In a large number of post-mortem examinations of the results of appendicitis, apart from this case, the speaker has not failed to recognize that perforation of the appendix, or inflammation without perforation, resulted from concretions in the appendix or from foreign bodies lodged in it.

He thought that the position taken by the author of the paper is not sustained by statistics. He agreed with Dr. Price that, in a large proportion of cases, the disease results from the presence of foreign bodies or concretions in the appendix, and he is convinced of the necessity for early operation in these cases.

In order that an operation should be successful it must be done early, and in all cases we should operate as soon as we suspect appendicitis.

A CASE OF INTESTINAL ANASTOMOSIS WITH CARTILAGE PLATES, FOR TRAUMATIC STRICTURE OF THE ILEUM—RECOVERY.[1]

BY M. STAMM, M.D.,
OF FREMONT, OHIO.

IN the evening of September 7, 1890, I received a telegram from Dr. Beardsley, of Ottawa, Putnam County, Ohio, worded: "Come immediately, prepared for abdominal work." I could not reach the doctor until noon of the next day, and on my arrival he gave me the following history:

"I was called on August 20th one and one-half miles east of Ottawa, to see a little son of Henry Agner, about seven years old, who had been run over by a loaded wagon. On my arrival I learned from the father, who was driving the vehicle, that his load consisted of gravel. The patient, with his brother, was upon the load playing, when the latter cried out: 'Mackey has fallen off and the hind wheel has run over him!' The father picked up the boy, who seemed not to be badly injured, and carried him to his own house, which was not more than two hundred rods away, and sent immediately for me.

"On inspection I could plainly see the mark of the wheel across the boy's body just below the umbilicus. There was paralysis of the lower extremities, but the boy did not complain of pain unless an attempt was made to move him. I applied a flannel bandage, well padded with cotton-wool, snugly around his body, but gave no medicine. On the next morning I found my patient quite cheerful, but having some pain. Ordered $\frac{1}{10}$ grain of morphine every hour until relieved. I saw him again on August 22d, and found him up and feeling well, as he expressed himself. On August 28th, he was suffering severely from disturbance of the bowels. His mother informed me that he had visited the grape arbor quite frequently during the last few days, and she suspected that he had overloaded his stomach with grapes which were not fully ripened. I prescribed a mild saline (Rochelle salt) but was sent for again on the same day and found that he had not retained the salt. I then prescribed an enema of table-salt and water, which brought away some feculent matter containing an abundance of grape-seeds. I did not visit him again until August 31st, when the pain became so severe that every breath was a moan. I also heard that no further movement of the bowels had occurred since the enema. I again prescribed Rochelle salt, but with the former results. By the use of morphine I was able to control the pain and make the boy somewhat comfortable until September 5th, up to which time there was no bloating of the abdomen, and flatus occasionally passed from his anus.

"From this time tympanites became very extensive, and morphine no longer controlled the pain. I now advised an operation, explaining the technique and endeavoring to make the parents fully understand the gravity of the procedure as well as the boy's present condition, but consent to operate was not given until September 7th."

When I saw the little patient in the afternoon of September 8th he presented tympanites to a high degree. There was no rise of temperature, his pulse was about 108 per minute, and he had vomited in the morning. As he was under the influence of morphine there was no pain on pressure. On examining the rectum I found it empty, and there were no signs of a tumor. Dr. Beardsley had

[1] Read before the Northwestern Ohio Medical Association, at Lima, Ohio, December 11, 1890.

explained to the family before my arrival the possibility of an injury to the bowels, of strangulation due to adhesive bands, or of a slit in the omentum, etc., with which I could only concur. I cannot let this pass without complimenting the doctor for the thoughtful manner in which he made the preparations necessary for an operation, so that in fact very little was left for me to do other than to proceed. I insert this compliment especially, because I think if every practitioner were imbued with the importance of an early operation in cases of obstruction of the bowels, instead of temporizing with all the different methods which are harmful because in many instances they injure the bowels and defer an operation too long—generally to the last stage—it would put surgeons in a position to report more successful cases than we have hitherto been able to do. Moreover, I think that in a number of cases collapse has been caused by the persistent efforts to move the bowels.

Operation.—An incision about three inches long was made below the umbilicus. The intestine was

FIG. 1.

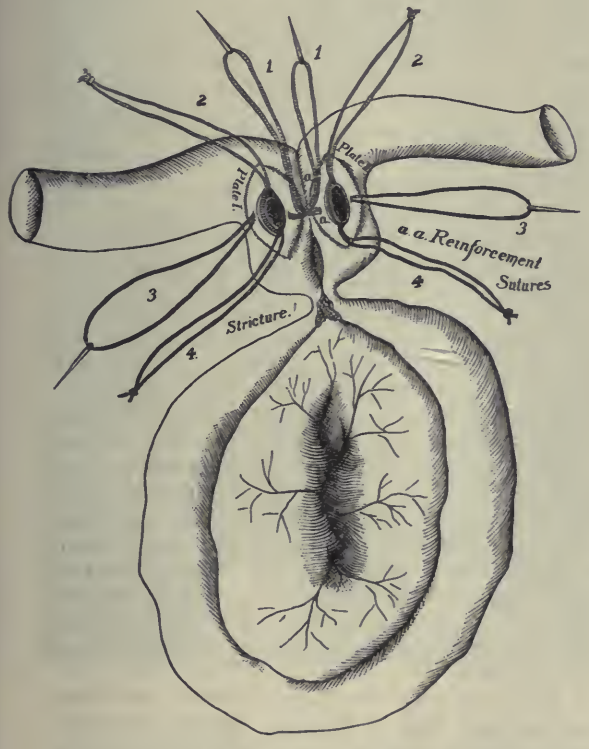

FIG. 2.

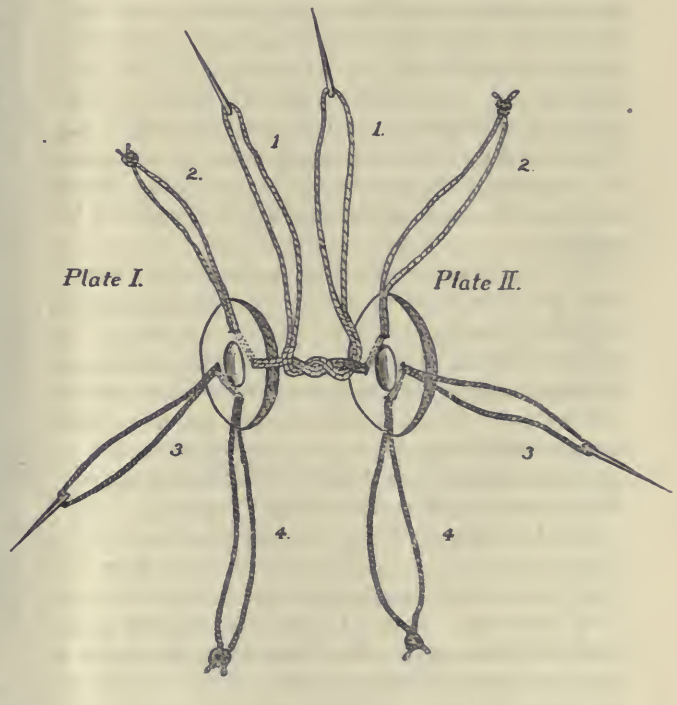

so distended that a portion several feet long forced itself through the wound and I had to puncture it in order to get at the seat of obstruction. As there was some bleeding from the puncture I closed it with two sutures. In groping for the cæcum I found an empty coil of the ileum, and, about ten inches from its insertion into the larger intestine, a double stricture revealed itself, of which the accompanying illustration (Fig. 1) may give an idea.

The mesentery of both segments had evidently been lacerated, and judging from appearances the outer coat of the ileum also was injured near its mesenteric attachment, so that the cicatricial contractions, combined with the agglutination of both mesenteries were sufficient to form a stricture which would hardly admit a small lead-pencil. I therefore decided upon intestinal anastomosis, without resection of the strictured coil, which was nearly twelve inches long. In order to prevent the escape of intestinal contents the bowels were compressed by means of elastic bands passed through the mesentery and fastened on the convex side of the intestine with small hæmostatic forceps. As one of the loops was not sufficiently emptied of its contents, probably owing to the fact that by handling the strictured coil some mucus and feculent particles were squeezed into the emptied coils, a small quantity of mucus and fæcal matter escaped on incision and somewhat soiled the field of operation. The soiled parts were immediately and thoroughly irrigated with warm water. After incisions about three-fourths of an inch long were made in the afferent and efferent coils, I introduced medium-sized plates armed with *black* and *white* threads in the manner that I demonstrated last year.[1] I also used five reinforcement sutures and after a second irrigation of the extruded parts I dropped them into the abdominal cavity.

With the exception of an abscess over the parotid region, which was opened by Dr. Beardsley on the eleventh day, the boy made such a rapid recovery that he was able to visit the county fair on October 2d. His bowels moved spontaneously on the third day after the operation. The plates were never

[1] THE MEDICAL NEWS, February 1, 1890.

found in the stools.[1] Judging by the amount of food which he consumes, there is little probability that the anastomosed opening will ever have a chance to contract.

A few words may be said in regard to the plates. Senn's bone-plates, when properly prepared, seem to answer the purposes in every respect, in point of coaptation as well as absorbability. Any modification of them could be made only in the direction of simplicity, as it is well known that their preparation requires an undue amount of work and time. All this, as I demonstrated before the Northwestern Ohio Medical Association last year, I have overcome by cutting my plates from the lower angle of the shoulder-blade of young cattle (not calves, as the latter would be too soft). This portion of the scapula is cartilaginous, and of sufficient firmness, and can be readily cut with a penknife, in fact the preparation requires only a few minutes. The fear that such plates would be too rapidly absorbed, as maintained by some experimenters, is, in my opinion, more the product of exuberant fancy than the result of careful experimental or clinical observation. I have kept them in a warm solution of salt and found them after forty-eight hours nearly as firm as at the time I put them in. Should such a fear exist, as for instance in anastomosis of the upper portion of the intestinal tract or the stomach, it is only necessary to cut a little deeper into the bony portion of the scapula, when any consistency that is desired will be found.

Dr. Senn, in his paper read at Nashville, Tenn., May 21, 1890, made an erroneous statement, though not intentionally, when he said: "Dr. Stamm, of Fremont, Ohio, made plates of the thin portion of the scapula of a calf, and used them in a gastro-enterostomy for carcinoma of the pylorus. The patient died forty days after the operation, and at the necropsy the plated inserted in the stomach was found unchanged in this viscus." I said:[1] "But, again, I do not think it necessary to use *undecalcified bone-plates* for the gastric portion, as in my case it was found nearly intact in the stomach after forty-five days. I have of late prepared my plates from the lower angle of the shoulder-blade of young cattle (a heifer two years old). They can readily be cut with a knife, and are ready for use in half an hour. . . . ." The fact is, that the thought of using cartilage plates suggested itself to me after I made my gastro-enterostomy; for that particular case I used for the stomach a *slightly decalcified bone* from the tibia of an ox. As I have demonstrated before, I also deviate from Dr. Senn's way of arming the plates: his *lockstitch* seems to me a complicated one, and has not the slightest advantage over my method. I do not drill any holes for the threads in my plates, as they can be readily transfixed by the threaded needle. The use of black and white thread has also materially lessened confusion in tying the knots, a thing which will, no doubt, be appreciated by those who have so far used threads of but one color. The only point to be observed is (see Fig. 2) that the white thread should, for instance, transfix plate No. 1 on the right side and plate No. 2 on the left side, and then be tied in their respective order, as shown by the numbers.

[1] The boy was present at the meeting and was a picture of perfect health.

[2] THE MEDICAL NEWS, February 1, 1890.

A CASE IN WHICH CYSTIC DEGENERATION OF THE KIDNEYS OF A FŒTUS PREVENTED DELIVERY.

BY M. HOWARD FUSSELL, M.D.,
CHIEF OF THE MEDICAL DISPENSARY OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

MY friend, Dr. A. H. Mellersh, of Roxborough, called me to see a case of labor on the morning of October 22, 1890, and to him I am indebted for the privilege of describing this interesting specimen.

Mrs. X., aged twenty-eight years. Third labor. Her first child was born healthy and is still living. The second child was born eighteen months ago. The head and shoulders were born without trouble, but considerable difficulty was experienced in delivering the abdomen. The child lived for a few minutes only, and a certificate of death from malformation of the kidneys was given.

The last pregnancy was not attended by any special symptoms, except, perhaps, an unusual amount of abdominal pain.

Dr. Mellersh was called about 4 o'clock on the morning of October 22d. The vertex presented, and the head descended and was delivered without trouble, but further progress was not made. The doctor then delivered the arms and made forcible traction, but without delivering the child. At 6 A.M. I was called and found that as much traction as was permissible had been made. The woman was etherized, and on introducing my hand into the uterus the enormously distended abdomen of the child could be easily felt. The child, of course, was dead. The distended abdomen was punctured, but only a slight amount of fluid escaped. Further examination made it certain that the enlargement of the abdomen was due to a solid tumor, or rather what felt like a number of tumors.

The opening was at once enlarged and the child partially eviscerated. The liver and intestines came away first. One of the tumors was then grasped, traction made, and the infant easily delivered. The mechanism was, doubtless, that one tumor was pulled ahead of the other, thus at once diminishing the girth of the child's abdomen and permitting delivery.

The infant was a rather large male. The abdo-

men was much enlarged, and measured eighteen inches in circumference at umbilicus.

On examination the following conditions are seen: Both kidneys enormously enlarged; the left measuring six by five inches, the right five by four inches. Both still have their original form, are lobulated, and are the seat of cystic degeneration. The mass is composed of a multitude of small cysts, varying from the size of a pea to that of a pin-point.

On section the cysts are seen to be filled with a clear fluid resembling urine. The left kidney is connected with the lower part of the abdomen by strong bands, which are apparently folds of the peritoneum and not adhesions. The hilum is near the lower end.

The ureters are plainly seen as small white cords, running over the lower end of the kidneys, and leading into the empty, contracted, elongated bladder. They are patulous. The pelves are buried in the mass of cysts. The bloodvessel supply is normal. The suprarenal capsules are enlarged. The heart is much hypertrophied, is about three times the normal size, and feels like a solid mass of flesh. The ventricles are small. The walls of the left ventricle are five-eighths of an inch thick, those of the right three-eighths of an inch thick. The valves are normal, but from the great thickness of the ventricular walls one would suppose that they were practically useless. The right testicle is in the abdomen, the left is in the abdominal ring. There were no other abnormalities noted.

The mother made a good recovery.

Congenital cystic degeneration of the kidneys is a well-known lesion, and has been the subject of numberless essays. Although infants with this condition are stillborn or die soon after birth, what is apparently the same condition has been found in adults.

Frequently the degeneration is connected with various other malformations, such as hydrocephalus, malformation of the genitals, etc.

The same woman has been known to give birth to several children with cystic degeneration of the kidneys.

In 1845 Virchow[1] carefully examined a case and expressed the opinion that the original seat of the cyst-formation is in the uriniferous tubules or in the Malpighian capsule, and that during the progress of the disease these cysts may lose their connection with the tubule from which they started. He believes that the original occlusion is frequently due to infarcts of uric acid salts, although it may be due to an inflammation starting in the pyramids. From the fact that the same woman may give birth to successive children with this abnormality, he thinks that the uric-acid diathesis in the mother may be the original cause of the trouble in the child.

Virchow's explanation of the process is accepted by most of the pathologists of to-day, although I think they repudiate the idea of the uric acid diathesis as a cause.

The normal kidney-substance is more or less destroyed in all cases, but in most there can be found here and there areas of comparatively normal kidney-substance.

Uhde[2] gives the notes of a case in which some of the glomeruli were normal, some were filled with yellowish epithelium, and some were entirely cystic. The cysts were lined with the epithelium common to the normal capsule. This case, to my mind, is convincing as to the capsules or tubules being the original seat of the cysts.

Though congenital cystic degeneration of the kidneys is so well known pathologically, it is extremely rare as a cause of dystocia. Most of the writers on the subject mention malformation of the kidneys as a possible, but rare, cause of dystocia.

In a rather careful search of the literature I have been able to find but eleven cases in which the kidneys were sufficiently large to impede labor, and only one case in which mutilation of the child was necessary. Doubtless other cases exist, but I have been

[1] Gesammelt Abhandlungen, p. 870.

[2] Monatsschrift für Geburtsheilkünde, 1856.

unable to find them. It will be interesting to cite a few of these cases.

Bruckner[1] cites the case of a woman who at two different labors gave birth to children with cystic kidneys. Both children were malformed in other respects. One of the children was dismembered in order to effect delivery.

Duffry:[2] Third pregnancy; breech presentation, cystic kidneys; hydrocephalic monster, with malformed hands and feet.

Siebold:[3] Child was also hydrocephalic; much difficulty in the delivery.

Carmack:[4] Child born at term; cystic degeneration of both kidneys. Much difficulty in delivery.

Oesterlen[5] gives the history of a case and a picture of the child with the kidneys in position.

There is an excellent bibliography of the subject in the *Dictionnaire des Sciences Méd.*, vol. iii., 3d series, page 294.

My case is the first of the kind presented to the Philadelphia Pathological Society. It differs from most of the reported cases in being, apart from the kidneys and associated lesions, a perfectly normal child.

The hypertrophy of the heart in this case is either unusual or, in other cases, has escaped notice, for in none of the reports do I find it mentioned. In some of the reports the heart is said to be normal, in others it is not specially mentioned. There seems to me to be every reason for hypertrophy of the heart in such cases, for although the heart of the fœtus is only secondary in supplying blood to the different parts, its work must be many times increased by the great resistance offered to the circulation not only in the kidneys themselves, but in the whole abdomen and chest, owing to the pressure of the greatly-enlarged kidneys.

It is interesting to note that in my case the hypertrophy is not limited to the left side of the heart, but is almost equally great on the right side. This would be expected, inasmuch as the right side is directly connected through the conus arteriosus with the general circulation, and hence must be affected by any undue pressure in that circulation.

The practical lesson of this case is: When difficulty is experienced in delivering the abdomen of a child, at once anæsthetize the woman, introduce the hand into the uterus and find the cause of the detention. If the child's abdomen is enlarged, and traction has been made, at once puncture the abdomen. In this case the instrument used was an ordinary pair of shears. An opening was made in the chest, my hand introduced into the abdomen of the child, and the operation continued as described.

I cannot imagine why an obstetrician should pull at the child for ten hours, as was done in one of Bruckner's cases, in which dismemberment was finally necessary, when evisceration is so easily and speedily performed.

SCIATICA, NEURALGIA, OR NEURITIS?

By L. HARRISON METTLER, A.M., M.D.
of Philadelphia.

While an indefinite terminology has frequently served as a convenient cloak for human ignorance, it has always more or less retarded the progress of scientific knowledge. Such names as gastralgia, myalgia, neuralgia, essential paralysis, consumption, and locomotor ataxia, may be very comforting to employ in certain obscure cases, but their careless and indiscriminate application to well-recognized symptom-groups and pathological states is an unwarrantable looseness in the use of language, and seems much like a confession of ignorance or of indolence. Not infrequently the use of such general terms becomes so soothing to one's conscience that all further effort toward a more accurate study of the case in hand grows irksome and seemingly unnecessary. Many cases of gastric ulcer and cancer have doubtless been neglected, at least in their incipiency, with the easy explanation that they were merely unaccountable gastralgias. There was no question as to the presence of the pain, and since science permits the use of the term gastralgia, it was employed, both for the sake of convenience and for its own peculiar scientific ring. The early pains of posterior spinal sclerosis have been notoriously mistaken for the pains of rheumatism; and as rheumatism has grown to be such a convenient name for all sorts of indescribable aches, acute and chronic, nothing is easier than to look wise and pronounce the pain rheumatic. Who knows how many years our knowledge of acute anterior poliomyelitis has been delayed by the high authoritative support which the name "essential paralysis of childhood" received when the disease was first described!

Neuralgia and neuritis are almost constantly being confounded with each other, and though many cases of so-called neuralgia are plainly instances of neuritis, it is much more convenient, in the hurry of general practice, to call cases of painful nerves by the undeniable but meaningless name of neuralgia than it is to study the electrical reactions and other symptoms characteristic of neuritis. Dana[1] found, after a close study of the subject, that true idiopathic neuralgia was a rare disease, constituting not more

[1] New York Medical Journal, 1887.

than two or three per cent. of the different forms of nervous disorders. Symptomatic and reflex neuralgias were far more common. These statistics confirm those of Classin, of Kiel, who collected 434 cases. And yet how many cases in general practice we hear of being diagnosed and treated as idiopathic neuralgia! This lack of careful study has retarded not a little our knowledge of the inflammation of nerves. Obviously here is a strong argument in favor of "specialties." The general practitioner may have frequent opportunities and, at times, superior ability for the study of these special diseases, but rarely does his inclination or time allow him to improve his opportunity or exercise his special ability.

In no single affection is the truth of the foregoing remarks more clearly illustrated than in that which is commonly described under the head of sciatica. It may be rash to dogmatize in regard to a disease which affords so few opportunities for post-mortem examination; nevertheless the majority of the supposed neuralgias of the sciatic nerve are beginning to be recognized as undoubted cases of sciatic neuritis. Both the symptomatology and the therapeutical results indicate such a condition. There have been considerable confusion and self-contradiction among the authorities upon sciatic neuralgia. Thus Flint declares that the affection ranks in frequency with facial and intercostal neuralgia, and that in the great majority of cases it is a functional affection. Then after giving a clinical picture of the disease which would serve as an admirable description of sciatic neuritis, he says, "sciatic neuralgia, rarely, as compared especially with facial neuralgia, exemplifies, in the recurrence of paroxysms, the law of periodicity." He describes the pain as always of a constant, boring character, unlike the ordinary, sharp, shooting pains of other neuralgias. He and many other writers whom I have consulted on this point, advance as an important symptom of sciatica the fact that the pain follows the course of the nerve and that the patient can thereby trace its anatomical situation; yet this is almost a pathognomonic sign of neuritis.

The etiology of sciatica is remarkably like that of neuritis and unlike that of the other neuralgias. Note a few of the causes of sciatica recorded in one of the recent text-books upon nervous diseases: Traumatism, exposure, gout, rheumatism, syphilis, and malaria. Lawson says that nine-tenths of the cases of sciatica are due to exposure to cold; while Erb insists upon the preëminence of this above all other causes. Not only are these found to be the most common etiological factors in decided cases of neuritis, but it is hard to understand in the light of our present knowledge of the nervous system how such factors can give rise to any other condition than that of inflammation. Surely it is a high degree of ultra-conservatism to admit that direct injuries, exposure to cold and poisoned states of the blood may and do give rise to inflammations in the brain, spinal cord, and other organs of the body, while in the nerves they produce only that kind of change of nutrition which is involved in the idea of neuralgia. It is a significant fact, when considered in this connection, that heredity and predisposition are of less importance in the etiology of sciatica than in neuralgia of the other nerves. Therefore, had not a single post-mortem examination of a painful sciatic nerve been made, the close similarity between neuritis and so-called sciatica in their etiology alone would incline us to believe that the latter is really a condition of inflammation.

In passing, it is interesting to note that Quenu[1] found in persons suffering from varicose veins, the veins in the interior of the sciatic nerves greatly dilated. Out of sixty-seven individuals with varicose veins, eleven were the victims of sciatica. A private case now under my care is that of a strong German woman, fifty-two years of age, with varicose veins of the right leg, who suffers at rare intervals with slight attacks of pain along the course of the corresponding sciatic nerve. An elastic stocking and the internal administration of hamamelis are affording her marked relief.

A comparison of the symptoms of sciatica with those of neuritis confirms still more forcibly the inflammatory origin of the former. It is oftener the rule than the exception for the inflammatory process in neuritis to be more intense at certain spots in the course of the nerve; indeed a large number of these cases might well be called *focal* neuritis, on account of the higher degree of inflammation at these points or *foci*. The pain, which is equally sharp if not sharper, in acute neuritis than in idiopathic neuralgia, which is almost as sudden in its onset, and at times quite as intermittent, is always most severe at these foci. What, therefore, are these tender points of neuritis but the long-recognized *puncta dolorosa* of neuralgia? Even in a general diffuse neuritis, the nerve is extremely sensitive and if it be pressed where it approaches certain bony prominences, the pain will be felt most keenly at those localities. In sciatica the puncta dolorosa are usually described as being situated in the neighborhood of bony prominences. According to Valleix, who first drew attention to them, these points correspond to the posterior superior spine of the ilium, the spine of the ischium where the nerve escapes from the pelvic cavity, the great trochanter of the femur behind which the nerve runs near the border of the gluteus maximus, the head of the fibula, the internal malleolus and

[1] La Semaine Medicale, 1888.

the dorsum of the foot. It is unnecessary to insist that at these points the nerve gives off large and important branches, for this only mystifies still more the explanation of the pain at these localities; furthermore, the explanation, whatever it be, will not apply to those inconstant points which sometimes appear at the middle of the thigh and in the calf of the leg. Pressure caused by the products of inflammation is a much more rational and physiological explanation of so common a phenomenon.

In neuritis it is easy to explain the tenderness of the nerve-trunk by means of the inflammatory irritation and pressure upon the nervi nervorum, but in neuralgia, in which there is supposed to be no perceptible lesion of the nerve-trunk, it is difficult to comprehend how such exquisite local pain can originate. Physiologists tell us that a nerve-fibre is sensory or motor according to its termination in sensory or motor organs. If, for instance, it is attached at its distal extremity to the tactile corpuscles of Meissner, the Pacinian bodies or other sensory-end organs, while at its proximal extremity it is associated with the sensory cells of the cortex, it is a sensory nerve. If, on the other hand, it begins in the large motor cells of the cerebral cortex or anterior horns of the cord and terminates in the motor end-plates of the muscular tissues, it is a motor nerve. Without these aids it is absolutely impossible to distinguish motor from sensory nerves, for in histological structure they are identical. A simple nerve-fibre, when separated from its end-organs, has no power to distinguish motor from sensory impulses. It is a question whether nerve-fibre can even perceive a sensory or motor impression unless that impression be received and evolved by a special end-organ. While the nerve-fibre is thus in itself entirely insensible, the nervi nervorum ramifying in its sheath cause it to appear extremely sensitive. These nervi nervorum have been demonstrated in the sheath of the optic nerve by Sappey and in other nerves by Horsley.

According to Magendie, Arloing and Tripier, most nerves receive recurrent fibres from adjacent nerves; these probably end in the nerve-sheath also, and being of different lengths may give rise to pain at different points in the course of the nerve-trunk. At all events, the fact remains as stated in the last edition of Kirke's *Physiology*:

"Nerve-fibres are stimulated to act by anything which, with sufficient suddenness, increases their irritability, but they are incapable of originating of themselves the condition necessary for the manifestation of their own energy. The stimulus produces its effect upon the termination of the nerve stimulated, being conducted to it by the nerve-fibre. The effect of the stimulus upon a nerve, therefore, depends upon the nature of its end-organ."

This is proved by the following experiment:

"A length of a nerve-trunk, when freshly removed from the body, if stimulated midway between its extremities, will, as shown by the deflection of a needle of the galvanometer at either end, conduct the electrical impressions in either direction and it may be considered therefore only an accidental circumstance, as it were, whether when *in situ* it has conducted impressions to the central nervous system from the periphery or from the central nervous system to the muscles or other tissues."

In neuralgia there is no change in the nerve-trunk so far as modern pathology can discover, so the nervi nervorum are not directly affected. There are no sensory cells along the course of the nerve to receive painful impressions and transmit them directly to the brain. Yet neuralgia is one of the most painful of all affections, and the pain, as in sciatica, is even more intolerable in the nerve-trunk than at its peripheral extremity. Those who deny the inflammatory character of these painful sciaticas have no easy task before them to explain the immediate cause of the pain. In opposition to all the teachings of physiology, they must show how an inert nerve-fibre, capable merely of transmitting centrifugally or centripetally the impressions which it receives, can, when unaffected by any perceptible source of irritation within or outside of its own substance, give rise to the most excruciating agony. Does it not seem singular that this mysterious agent can thus arouse to the highest degree the function of sensory nerves, and yet not affect the motor nerves? The motor nerves are like sensory nerves; yet *motor* spasm, pure and simple, is not a symptom of neuralgia.

The only way out of the dilemma, it seems to me, is to adopt the view that makes neuralgia a central disease, a kind of Jacksonian epilepsy, if I may be permitted the phrase, limited to the sensory areas of the cortex. The hypothesis, however, will be hard to maintain in conjunction with the many other symptoms of sciatica, of which I will speak later on.

In typical neuritis there are associated with the pain along the course of the nerve-trunk, peculiar sensations, paræsthesiæ, and various degrees of motor paralysis in the parts supplied by the nerve and its branches. The combination of these two sets of symptoms, pain in the course of the nerve and various spontaneous motor and sensory phenomena at its distal extremity, is almost pathognomonic of an inflamed nerve. Pressure upon the nervi nervorum and the recurrent fibres sufficiently explains the former, while interference with the power of conduction in the inflamed nerve-trunk itself readily accounts for the latter. Yet the books assert that in simple neuralgia of the sciatic nerve there occur various paræsthesiæ, tonic and clonic spasms in the leg, and even considerable degrees of paralysis; in other words, when the nerve is apparently

unchanged histologically, it is affected functionally in such a mysterious manner as to give rise to paralysis and symptoms of irritation at the same time. The argument itself is a *reductio ad absurdum*. The nerve, it is asserted, is so sensitive that the affection itself is worthy of the dignity of the special name, neuralgia; while at the same time the nerve is so dead as to fail in the proper conduction of received impressions. Usually, irritation is the cause of muscular spasm; here, however, irritation is made more frequently to accompany paralysis. There is a conflict here between physiology and pathology which those who insist upon the non-inflammatory character of sciatica will do well to explain.

Again, it is written that inflammatory symptoms are wanting in idiopathic neuralgia; but in typical cases of subacute and chronic neuritis there are scarcely ever marked signs of active inflammation. Indeed, so insidious are the changes in certain forms of neuritis, that some have been led to doubt whether the condition is one of inflammation and not one of degeneration—a pathological process to which the nervous tissue is everywhere particularly liable.

Many authorities assert that at the height of a paroxysm of sciatica there are vomiting, anorexia, mild fever, constipation, high-colored saccharine urine, and delirium. They reason that these symptoms are the results of the general irritation caused by the intolerable pain. Mental irritation has, doubtless, a great deal to do with them, but it looks very much as though some of the symptoms, such as the pyrexia, constipation, and high-colored urine were due to an inflammatory process. It is no argument in favor of the neuralgic character of sciatica to say that febrile symptoms are usually absent, and the health but little impaired; for in nearly all cases of subacute and chronic interstitial neuritis there is little or no fever, and but slight, if any, impairment of the general health.

Most writers on the subject assert that wasting of the muscles in sciatica is due simply to their inactivity. Fagge notes that Anstie found the faradic excitability of the gastrocnemius much diminished in one case, and then justly observes, without apparently seeing the full force of his own observation, that "it is a mistake to suppose, with some writers, that the loss of power depends merely upon disuse of the muscles." So decided a symptom would have led almost any neurologist of the present day to infer an organic lesion of the nerve or the central origin of the disease, whether of the degenerative or inflammatory type, and the existence of such a lesion would have removed the disease from among the true neuralgias.

In neuritis the electrical reactions, myotatic phenomena, and trophic symptoms are the most positive and easily explained signs of the disease. The gradual destruction of the nerve must obviously result in a loss of reflex action, because of the break that is thus produced in the reflex arc. Various trophic disturbances, such as muscular atrophy, herpes, excessive perspiration, and effusions into the joints, are caused by the separation of the trophic and vasomotor centres of the cord from the parts innervated by the affected nerve. The explanation of the electrical phenomena, namely, diminution of faradic and increase of galvanic irritability, rests more upon theoretical grounds than does the explanation of most of the trophic symptoms; nevertheless, the fact that the reaction of degeneration is one of the most reliable evidences of the destruction of nerve-fibres remains still uncontested.

How are we to explain the formidable array of trophic symptoms attributed in most of the text-books to sciatic neuralgia, a disease in which it is not supposed that there are any histological changes, but only a functional change? Indeed, it seems easier to believe, as some have already been inclined to do, notably Vulpian, Anstie, Clifford Allbutt, and Vanlair, that neuralgia is often not a disease of the nerve itself, though localized in the nerve, but rather an affection of the central nerve-cells. It is certainly more rational to believe this than that a mere bundle of motor and sensory fibres which physiology teaches us are alike, can, without any other lesion than a mere perversion of function, give rise to a host of trophic symptoms of the most varied kind.

In simple neuritis posture is at times almost as pathognomonic as is pain upon movement. In true neuralgia posture usually affords no more relief than does simple movement cause increased pain. The faulty attitude of the body in sciatica is an old and well-recognized symptom. Sometimes the patient leans toward the painful side, sometimes away from it, but always in a direction to modify the intensity of the pain. Babinski[1] has presented some admirable illustrations of this posture-symptom in sciatica. In the latter disease the inclination of the body is toward the healthy side, while the foot of the affected limb rests flat upon the ground. By this manœuvre the nerve is probably lifted away from certain prominences in the pelvis against which it usually lies, but it is difficult to offer a completely satisfactory explanation in view of the two cases reported by Bouchard, in which the inclination of the body was toward the painful side. At all events, the fact remains that the assumption of posture is more strongly indicative of neuritis than of simple neuralgia.

Neuralgia of other nerves develops under very different conditions from those under which neural-

[1] Archives de Neurologie, January, 1888.

gia of the sciatic usually occurs. Furthermore, in true neuralgia the pain is spontaneous, generally sharp from the onset, and is felt at other times in other nerves. The victims of true idiopathic neuralgia of the sciatic nerve are apt to have at times migraine, neuralgia of some of the cranial nerves and of the viscera. These neuralgic attacks are remarkably disposed to become periodic. The majority of the cases of sciatica, however, occur after some cause or under some condition of the general health that is liable to give rise to inflammation.

If the pain of sciatica is transferred to any other part of the body, it is usually to the corresponding nerve of the opposite side. This one of the peculiarities of neuritis, and is probably due to a central irritation at the point where the two nerves approximate each other both anatomically and functionally. Headaches and visceral pains are very infrequent in patients suffering from sciatica if the disease is primary and not due to a mechanical cause, such as a tumor, constipation, or pregnancy.

In the treatment of sciatica so many different plans have been tried and the average results have been so unsatisfactory that one would almost be inclined to imagine that the disease is incurable or that its nature is not clearly recognized. Subacute and chronic neuritis are proverbially hard to cure. In the management of sciatica the methods that afford the greatest success are not only different in many respects from those employed in the treatment of other neuralgias, but they are identical with those that prove most efficacious in the management of inflammation. Counter-irritation and the actual cautery, the internal administration of vasomotor sedatives, and the free use of cathartics, diuretics, and diaphoretics act more favorably in sciatica than in neuralgia of the other nerves. Narcotics and sensory depressants relieve the pains of sciatica as they do all other kinds of pains, and for that reason are commendable; but they do not cure the disease so frequently as they do idiopathic neuralgias of the cranial and intercostal nerves.

According to Pliny,[1] the victims of sciatica in his day had their pains mitigated by the soft tones of the flute. From this ancient musical method to the modern hypnotic is not so wide a leap as would at first appear. It is a well-observed fact that pain may become a habit which often needs only moral and mental treatment for its relief. It is then like certain forms of habit-chorea. The pains of sciatica are experienced because the patient retains a vivid recollection of a past attack and fears a repetition of the same. In such cases, and they are usually long-standing ones, electricity, baths, moderate exercise, general hygienic and mental treatment will do much toward effecting a cure.

But these cases are not the majority. The larger number of sciaticas seem to be benefited by therapeutic measures which rational medicine would naturally suggest were the disease recognized as inflammatory. Drugs which control the inflammatory process as well as paralyze the sensibility, like antipyrine, aconite, and belladonna, are found to be the most useful in sciatica, while simple alteratives and nerve anodynes, such as the chloride of ammonium, menthol, arsenic, and iron, give the best results in the prolonged treatment of cranial neuralgias.

Nerve-stretching is sometimes a most gratifying therapeutic resource. In old cases of neuritis it doubtless acts by breaking up adhesions and restoring the circulation; in simple neuralgia, however, in which there are no perceptible organic lesions, it is difficult to explain its *modus medendi*.

When we thus consider the causes, symptoms, and therapeutics of sciatica, and compare them with the causes, symptoms, and therapeutics of neuritis, we are almost compelled to believe that the former is only a variety of the latter affection. When in so many respects two diseases are so similar, and when nothing is known of the pathology of one while the pathology of the other is a perfectly familiar picture, it is safe to conclude that, with possibly the rarest exceptions, the pathology is the same in each. It is easier to prove a rational hypothesis than one which is based on nothing better than imagination. We are totally ignorant of the pathology of neuralgia, and up to the present time all explanations in regard to it have been but little better than guesses. We do know a great deal, however, about the pathology of neuritis, and also how the disease gives rise to the particular set of symptoms which usually accompany this affection. The broad meaning of the term neuralgia—covering, as it does, so many different conditions, of which pain alone is the preeminent symptom—hinders not a little that close scientific accuracy which is so desirable in nosology and so necessary to the continued progress of knowledge. For the present, at least, we may assert that all appearances warrant the advanced conclusion that sciatica is usually a neuritis of the sciatic nerve. If this assumption be not true its error will be more quickly discovered, than if all sorts of painful conditions of the sciatic nerve are regarded as neuralgias of which there is no pathology known to modern medicine.

1938 NORTH BROAD STREET, PHILADELPHIA.

DR. L. WEBSTER FOX has just been appointed ophthalmic expert to the Board of Pension Examiners of the Philadelphia district.

CASES OF VERTEBRAL DISEASE AND OF FIBROID AND CYSTIC TUMORS.[1]

BY W. M. HARSHA, M.D.,
OF CHICAGO, ILL.

Two cases of vertebral disease.—The first two cases which I wish to report are so nearly alike that they may for the most part be considered together. They are cases of vertebral disease, supposed to be of tubercular character. Both are males, aged twenty-seven and twenty-eight years, respectively, of tubercular family history and lymphatic temperament. Each contracted the disease while occupied at office-work, one sitting at a desk in a strained position, the other standing at a high desk in a post-office. In each case the disease had existed for some months before the patients came to Chicago for treatment, and each had been treated for rheumatism, lumbago and kindred troubles.

The first case had a history of periostitis of the tibia, with exfoliation of the bone, probably tubercular, ten years before. When he came under the care of my associate, Dr. Stillians, and myself, the patient's temperature varied from normal to 101°. He had stiffness of the back in the lumbar region, and some pain radiating from this region to the lower part of the abdomen and front of the thighs. There was tenderness over the spinous processes of the upper lumbar vertebræ on percussion or pressure. Irritability of the bladder was another symptom, micturition occurring with more than usual frequency. There was difficulty in stooping and in going down stairs, the patient partly supporting himself by the railing. He also supported himself while in a sitting posture, by pressing on the thighs and hips with his hands. All the symptoms were aggravated by exercise, and there was difficulty in lying in any position other than on the back. There was no deformity, although slight induration could be detected along the sides of the spinous processes. Owing to the direction of the normal curve at this point, the convexity being anterior, we should expect less deformity than in similar disease of the dorsal vertebra; and in adults degeneration of bone takes place more slowly than in children, in whom this disease is most frequently encountered.

A diagnosis of vertebral disease was made by Dr. Stillians and myself, after repeated examinations. Professor William E. Quine, of the College of Physicians and Surgeons, and Professor Daniel R. Brower, of Rush Medical College, were afterward consultants in the case, and the diagnosis was confirmed, although there was some discussion as to the presence of a chronic inflammation of the meninges of the cord at this point, instead of vertebral disease. The differentiation from rheumatism was based on the long duration without the occurrence of other rheumatic symptoms, and on the strictly localized tenderness; and the diagnosis was further corroborated by the family history and previous periostitis.

The treatment was what any surgeon would have adopted, namely, rest, alteratives, tonics, and counter-irritants. The means adopted to procure absolute mechanical rest in this case was recumbency in bed. The patient was very anxious to recover, and gave us intelligent coöperation. Improvement in the symptoms, though not rapid, was appreciable within a few weeks. The fever subsided first, the irritability of the bladder yielding more slowly. The patient continued to have a good appetite, and increased in weight; the tenderness over the spine gradually diminished, and the pains about the lower part of the abdomen and thighs disappeared. After four months in bed, the patient was allowed to walk about with the aid of crutches and a corset-brace. The brace was of a kind in frequent use in cases of vertebral disease, consisting of a firm, well-padded waistband of steel, two steel supports fitted to the curve of the back, with attached shoulder-straps to counteract the tendency to inclination forward, and two side-stays made adjustable to different heights, to support the shoulders. Fitting inside, and attached to the upright stays, is a corset stiffened with whalebone, which serves to secure the body more firmly. The patient has returned to his home in Dakota and resumed his business. He still wears the brace, and continues to grow stronger.

The second case, some of the features of which have been mentioned, presented a similar history, the spinal tenderness occurring in the dorsal region, where there was also some degree of prominence or projection scarcely amounting to deformity. The natural curve of the spine at the seventh, eighth, and ninth dorsal vertebræ renders a very slight projection noticeable.

The symptoms differed from those of the first case in accordance with the different location of the diseases. There were pains of a neuralgic character in each side, slight cough, dyspnœa at times, and a feeling that a "full breath could not be taken." There was difficulty in going down stairs, and in lying in any position except on the back. As this patient was of more active habits than the first case, and for some time had been accustomed to out-of door life, it was thought best to permit him to go about cautiously with a plaster-of-Paris jacket on. He was impressed as much as possible with the importance of rest, but it was difficult for him to grasp the full significance of the term. His improvement has accordingly been more slow and interrupted. He seemed to be improved by cautious partial suspension, which was practised by means of Sayre's apparatus two or three times each week. He received the same general treatment as the first case. After two months the plaster-of-Paris jacket was replaced by a brace similar to that already described.

The improvement has been gradual. The tenderness over the spine and the neuralgic pains have disappeared, although they returned two or three times, as one would expect in a case not having the most watchful care as to exercise and exposure. He can now lie in any position in bed, go up and down stairs with ease, "carries" himself in a natural manner, and expects to return to his home in Texas very soon.

Among the interesting features of these two cases

[1] Read at the fifteenth semi-annual meeting of the District Medical Society of Central Illinois, at Decatur, October 28, 1890.

are their exceedingly chronic nature and the absence of deformity in one and almost an absence in the other. There was no history of injury in either case, but positions that taxed the spinal column caused fatigue.

Hilton cites a case which he attributes to fatigue from sitting on a seat at school. He states his belief "that the majority of the cases of primary disease of the spine in children, and almost all those in adults, are the results of exercise persevered in after fatigue—that is, after muscular exhaustion, or of accident, unacknowledged or overlooked." At the time that Hilton wrote it had not been definitely settled that a slight injury causing congestion or effusion is even more likely to determine a tubercular deposit in those so predisposed, than is a more serious lesion, such as fracture. He believed that the weakening or congestion of the part determined the inflammation, but the specific nature of the lesion had not been demonstrated.

The existence of tubercle in the cases I have reported is not demonstrable, but from our knowledge that such diseases are usually tuberculous, it seems probable. The greatest importance attaches to an early diagnosis in such cases, and a good deal of obscurity often surrounds them. If deformity exists, the diagnosis is easy; but although a cure is often effected after deformity has occurred, it is less certain, requires more time, and in growing children, in whom vertebral disease is most common, the angular projection is likely to increase before the health is restored.

In obscure cases pains referred to the stomach, abdomen, or other parts corresponding to the distribution of the spinal nerves, should be traced to their source. The decubitus and the carriage of the patient should be carefully observed. An apparent lateral distortion is sometimes noticed before angular projection is appreciable. A cough persisting without corresponding pulmonary conditions should excite suspicion. I remember the case of an adult which ended fatally, that came to me from the third physician by whom he had been treated. He had a deformity and was partially paralyzed, but had not been treated for anything except "lung trouble," so far as I could learn.

I saw another case in an adult soon after this at about the same stage of the disease. A diagnosis had been made, but at what time is unknown. The patient dragged one foot in walking, due to involvement of the cord. The brace on which the main reliance in treatment was placed gave very imperfect support. This patient, who died soon afterward, should have been kept in bed until his symptoms improved, or until a brace could be so adjusted as to secure fixation of the spine in a proper position.

Not all cases can be treated alike. Some patients cannot bear confinement in bed, and in such mechanical support is necessary. In some cases suspension may aid in relieving pressure and preventing deformity, while in others, in which the disease is inactive, a disturbance of latent or encapsulated tubercles may be caused by suspension, and degeneration become active.

Fibroid and cystic tumors.—I have two specimens of tumor, one of which is an example of the fibrous, the other of the cystic, variety.[1] The fibroid, which I removed from the breast of a married woman, aged twenty-two years, had been growing about two years, and was somewhat troublesome on account of the pressure made on it by the clothing.

The cyst was also of two years' growth. It was of the synovial variety, and was attached to the semimembranosus tendon, a part of the inner hamstring, from which it developed. It had become inflamed several times from bruises, and then was so sore as to interfere seriously with locomotion. Three weeks before its removal it had been accidentally injured and hæmorrhage had occurred within and around it, infiltrating the fasciæ and producing so much swelling as to obscure somewhat the form and extent of the cyst. The whole of the cyst was removed, and, on account of the extravasation, the wound was left open and packed with antiseptic gauze. The patient returned to his home in two weeks.

Natural bursæ are found in this region and sometimes connect with the knee-joint, but when they become cystic the communication is cut off. The cyst contained grumous blood with fibrinous semisolid portions, usually described as melon-seed bodies.

In this locality such tumors presenting in the popliteal space, and lying close to the arteries, may, by their pulsating character, be mistaken for aneurism; but by pushing the cyst aside, the pulsation disappears and a diagnosis is readily made.

58 State Street.

MEDICAL PROGRESS.

Treatment of Valvular Disease of the Heart.—In a recent address before the Hunterian Society, Dr. P. H. Pye-Smith (*British Medical Journal*, December 20, 1890) gave the following excellent summary of the treatment of valvular disease of the heart:

After referring to the value of digitalis, especially when given with squill and black oxide of mercury in pill-form, he said that strophanthus is often a useful substitute after the long-continued use of digitalis. In his experience strophanthus has given the best results in the treatment of mitral incompetence in children. Convallaria has a very similar, though weaker, action, and is better as a diuretic than as a direct cardiac tonic.

In aortic valvular disease, uncomplicated by dropsy or venous congestion, digitalis is frequently uncertain

[1] The specimens were shown to the members of the Society.

and sometimes dangerous. Iron when well borne, strychnine, and, in many cases, arsenic, are valuable; but often the most relief is afforded by careful attention to the diet, in order to insure perfect digestion and the avoidance of flatulence. The author has been disappointed in the effects of belladonna on aortic valvular disease. When there are pain, headache, and symptoms resembling those of aortic aneurism, or attacks resembling angina pectoris, nitroglycerin and nitrite of amyl are extremely valuable remedies; but in many cases the application of leeches over the sternum, or small and repeated bleedings from the arm, are more efficient than any drugs. Ether, particularly in the form of Hoffmann's anodyne, strychnine and aromatic spirit of ammonia, are very useful in the cardiac dyspnœa and distress which accompany most cases of aortic disease.

In advanced cases of mitral disease with anasarca, opium is usually contra-indicated. But in disease of the aortic valves opium, in the form of laudanum or Dover's powder, may frequently be given at night with great relief and no bad effects. In such cases the opium should be given by the mouth rather than hypodermically. Potassium bromide and chloral often produce unpleasant effects; and in cases of restlessness and discomfort, tincture of hyoscyamus, given in hot brandy and water, is useful.

For the severe headache which often accompanies cardiac disease, antipyrine is sometimes given, but is dangerous and uncertain. Paraldehyde has been much used to secure sleep, but it often fails. Chloralamid, given in twenty-grain doses, frequently acts extremely well, and the author has seen no ill-effects from it, except dermatitis in one case. Sulphonal has also proved useful in his experience.

Another important point in the treatment of cardiac disease is the proper employment of venesection. In cases of aortic disease, when the pain and other symptoms resemble aortic aneurism, the abstraction of from four to six ounces of blood is sometimes very effectual, but less frequently than in cases of aneurism. When the right heart is distended, the whole venous system engorged, the skin cyanotic, and the pulse small, weak, and fluttering, moderate bleeding will sometimes give relief, but is seldom of lasting benefit.

Referring to Oertel's treatment of heart-disease by regulated gymnastics, Dr. Pye-Smith said that to him it did not seem to have either physiology or experience in its favor. Cardiac gymnastics are already provided for by the necessities of the circulation, and there is no fear of the heart being too idle, but, on the other hand, great fear of its being taxed beyond its strength.

Guermonprez's Method of Reducing Backward Dislocation of the Femur.—Dr. CATOIR describes Guermonprez's method of reducing backward dislocations of the femur as follows:

The pelvis is fixed by the left hand of the operator placed upon the iliac spine, his right hand then grasps the patient's leg, the knee being in a position of extreme flexion, and forcibly flexes the slightly-abducted thigh until its anterior surface rests upon the abdomen. To-and-fro movements of inward and outward rotation are now executed until the head of the femur rests against the acetabulum, when direct pressure, either by the hands of an assistant or the knee of the operator, completes the reduction. During the last part of the manipulations the extreme flexion of the thigh upon the abdomen should be slightly relaxed. The method is most useful in old cases, and particularly when the operator is without assistance. Guermonprez employed it [presumably successfully] under anæsthesia in an iliac luxation of eight weeks' duration, having on the previous day rendered the head of the femur mobile by means of flexion.—*Annals of Surgery*, December, 1890.

The Symptoms and Treatment of Diabetic Coma.—SCHMITZ (*Berliner klinische Wochenschrift*) recognizes two distinct varieties of diabetic coma. The first is due to weakness of the heart, caused by the effect of the sugar in the blood upon the muscular fibres. In such cases the face is cyanotic, the respiration rapid, the pulse slow and small, becoming rapid and irregular on exertion, the cardiac impulse is scarcely perceptible, and the first sound almost inaudible. In order to prevent coma in such cases everything that excites the heart must be avoided and exercise must be limited. All potassium salts including the bromide, salicin and its compounds, antipyrine, antifebrin, and hot baths are contraindicated. Narcotics should not be used unless they are absolutely necessary. The treatment of the diabetes must not be neglected. If the symptoms are very marked the patient must not be allowed to rise from the recumbent position for any purpose. Black coffee is the best stimulant to give by the mouth, and if it causes vomiting musk or camphor may be given hypodermically. Schmitz makes it a rule not to permit the patient to rise until the first sound of the heart becomes clear.

The second form of diabetic coma the author considers an acute self-infection, incorrectly called acetonæmia. This condition is preceded by symptoms mistaken for indigestion, namely, lack of appetite, eructations of offensive gases, sleepiness, etc. Sleep is unrefreshing; there is usually constipation, sometimes diarrhœa, and the tongue is dry and coated. These symptoms continue for about two days, when the patient becomes restless and drowsy; the respirations increase to 45, the pulse to 130 or more, and the temperature is somewhat elevated. The patient can be aroused from his sleepy condition by a loud call, but immediately relapses into semi-stupor. He complains of thirst and of pain in the upper part of the abdomen, which, however, is not tender. The pain may be paroxysmal and intensely severe. After violent efforts vomiting of greenish fluid occurs, and the pain is somewhat relieved. A physical examination of the lungs reveals nothing abnormal. The pupils are usually contracted and do not respond to light. Later, violent tonic and clonic spasms occur, and death in coma follows.

In the treatment of this form Schmidt recommends the administration of one or two tablespoonfuls of castor oil, whether the bowels are constipated or not. The purgative is given in order to remove the products of decomposition in the bowels, these products being the cause of the symptoms. After purgation the symptoms rapidly disappear. Of eight cases of this variety in the author's experience, four not treated with the oil died, and the remaining, treated with it, speedily recovered.—*Medical Chronicle*, November, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

SATURDAY, JANUARY 10, 1891.

A STATE BOARD OF MEDICAL EXAMINERS.

IT needs little argument to prove that the productive energy and wealth of a community depend directly upon the health of its individual members. Any factor, therefore, which prevents the occurrence of disease or which shortens the duration of disability from unavoidable disease or injury conduces to the welfare and progress of the State. It cannot be gainsaid that an essential in every well-regulated community is the assurance to the citizen that the person to whom he intrusts himself for medical treatment shall have an average knowledge of medical science. The principle involved is the same as that which has led governments to insist upon licences being obtained by pilots, steamship engineers, apothecaries, and others, before they assume to offer their services to the public.

The Act to establish a State Board of Medical Examiners and Licensers, which is published in this issue of THE MEDICAL NEWS, has this object in view, and ought to receive the earnest support of every intelligent reader.

The amount of suffering due to unnecessarily prolonged illness due to ignorant medical attendance, and the cost to the State of supporting in poor-houses disabled artizans whom early intelligent treatment would have made self-supporting, is scarcely realized by physicians themselves, and is an unknown quantity to the average layman. Unfortunately, too, it is usually those least able to bear an enforced abstinence from remunerative work who fall into the hands of uneducated or imperfectly-educated practitioners of medicine.

The purchase of bogus diplomas, the ignorance of many graduates coming from low-grade or poorly-equipped schools, and the expulsion of such ignorant practitioners from eighteen other States having boards of examiners, have flooded Pennsylvania with men totally unfit to have the care of the sick or injured. The necessity for a law requiring all *newcomers* to show evidence of fair medical knowledge before settling for practice in Pennsylvania has thus become imperative.

Official reports show that in the United States there have existed at least eighteen colleges from which diplomas could be purchased without the purchaser having studied medicine. How many possessors of these bogus diplomas are now posing as competent physicians is unknown. It is known that there have registered as physicians in Pennsylvania since the present defective registration law was enacted in 1881, at least 932 persons who have no diploma. In Allegheny County alone there have been about 100 such cases, and nearly as many in Philadelphia County. Nearly ten per cent. of all registered practitioners in Pennsylvania are without that slight evidence of medical education which even the poorest diploma gives. From official sources the fact is apparent that at least 222 persons have registered in Pennsylvania who possess diplomas from schools known to have been engaged in selling bogus diplomas.

The present law for the registration of physicians is notoriously imperfect in its results, so far as protecting the public from incompetence is concerned. This is due to the obscure wording of the law, which renders more than one interpretation possible in important sections, and to the circumstance that it places the carrying out of its provisions upon clerks in the offices of the Prothonotaries. These persons often are unfamiliar with the appearance of medical diplomas, frequently have no knowledge of the existence or non-existence of schools purporting to have issued any particular document, and are frequently being succeeded by other clerks even less familiar with such matters than themselves.

It is more than probable that these and other causes have permitted illegal registration in every

county of the State. Wherever careful inspection of the Prothonotary's records has been made by competent observers, numerous examples of improper registration have been found. In a series of eight counties, none of which contained large cities, forty-nine palpable instances of such illegality were recently found. In at least one populous centre this irregularity is known to be even worse.

The bill as now drafted, and which will be presented to the Legislature at an early date, is one fair in all its details. The candidate for license to practise must be a graduate, his paper is examined by those to whom his identity is unknown, his examiners are unconnected with medical schools, and he can select the system of materia medica and therapeutics in which he wishes to be examined.

The Executive, who appoints the Board, is untrammelled, except that he must give representation to at least nine different counties. Hence, none of those who believe in special systems of medical practice need fear exclusion from representation on the Board.

The recognition of diplomas and the determination of the physician's fitness to practise are now controlled by similar boards in States aggregating a population of about 20,000,000. The satisfactory result of such control indicates that Pennsylvania will be benefited by similar legislative action, and especially so, as this Commonwealth is now one of the States to which the ignorant and bogus practitioner gravitates because excluded from practising in those States whose people are protected by effective laws.

Let Pennsylvania do as has been done by North Carolina, South Carolina, Alabama, Illinois, West Virginia, Virginia, Colorado, Mississippi, Minnesota, Iowa, Missouri, New York, Montana, New Jersey, California, Florida, Tennessee, Oregon, and Canada, and her tax rate for the maintenance of almshouses can be diminished.

In the States of Maine and Maryland similar Acts have been passed by the Legislatures, but in each instance vetoed by the Governor. It is probable, however, that these States will, at an early day, again pass such laws, and join the number which believe that incompetent and ignorant physicians are a menace to the welfare of the State.

THE NEW SURGEON-GENERAL.

THE appointment, by the President, of Colonel Charles Sutherland to the position of Surgeon-General of the United States Army, with the rank of Brigadier-General, cannot fail to be well received by many of the profession, and by the branch of the service of which he is a member. By the rule of seniority, Dr. Sutherland had a claim to the appointment, and we believe that this fact had something to do, as it should, with the President's decision. While THE MEDICAL NEWS favored the cause of Dr. Billings, it cannot but believe that the medical department of the Army will be well cared for, since the present chief has had so much experience as to render his capability of dealing with his new duties undoubted. Dr. Sutherland entered the service in 1852, being appointed from Pennsylvania, and has a record untarnished both in professional and Army life.

REVIEWS.

MANUAL OF WEIGHTS AND MEASURES, WITH RULES AND TABLES. By OSCAR OLDBERG. Third edition, revised. Chicago: W. T. Keener, 1890.

To those who are already familiar with this useful little book it is unnecessary to speak well of it, and to those who are not fortunate enough to possess it we would earnestly recommend its purchase, particularly if they are engaged in pursuits which bring them in contact with the metric system or with accurate measurements. The very large number of books intended to provide for similar wants may, perhaps, be useful, but Prof. Oldberg has surpassed them, as much that is usually uninteresting is presented in so clear a manner that one cannot fail to understand what he reads on a single reading, while the tables are models of completeness. We believe that, if this book could be put into the hands of many medical students, it would not only be of great service to them during their college life, but be a valuable hand-book for reference in after-practice.

THE MICROÖRGANISMS OF THE HUMAN MOUTH, AND THE LOCAL AND GENERAL DISEASES WHICH ARE CAUSED BY THEM. By WILLOUGHBY D. MILLER, D.D.S., M.D. Illustrated. Philadelphia: The S. S. White Dental Manufacturing Co., 1890.

DR. MILLER'S book is not only interesting because of the studies and results which it details, but also because the author is at present one of the Professors in the University of Berlin, and a graduate of an American dental school, namely, the Dental Department of the University of Pennsylvania.

The volume is rendered particularly attractive to those who are interested not only in diseases of the mouth, but in bacteriology in general by reason of the very clear and well-executed cuts which are found on almost every page, while in addition to these will be found mounted photographs of the microörganisms which have been studied.

It has been said by some dentists that they fail to understand why the following of their profession did not

place them upon the high professional and social standing attained by doctors of medicine, and the real reason lies in the failure of most of them to do any original work save that which has a direct pecuniary reward. This book is, therefore, particularly refreshing, as showing that at least some members of the dental profession are awake to the necessity of careful scientific research and observation. Dr. Miller's book should be in the hands of every dental and oral surgeon, and if it is not successful, the author can rest assured that the fault does not lie with himself, but with his professional brethren.

Disorders of the Male Sexual Organs. By Samuel W. Gross, A.M., M.D., LL.D. Fourth edition. Revised by F. R. Sturgis, M.D. Philadelphia: Lea Brothers & Co., 1890.

Dr. Gross's book upon disorders of the male sexual organs is so well known to most of the profession, both in this country and abroad, that it is hardly necessary to do more than make a note of the fact that the fourth edition has appeared under the editorial care of Dr. Sturgis. Everyone who knows Dr. Sturgis's writings will at once recognize the fact that the publishers have done well in obtaining so thoroughly qualified an editor for so successful a book, and it is no reflection upon its author when we add that Dr. Sturgis's touch has improved the volume.

Progressive Exercises in Medical Chemistry. By Henry Leffmann, M.D., Ph.D., and William Adam, M.A., Ph.D. Philadelphia: P. Blakiston, Son & Co., 1890.

This little book, which is bound at the upper margin instead of upon the left-hand side, in order to make it more convenient for the table of the analytical chemist, will, no doubt, prove valuable to those professional men who desire to carry out certain experiments or tests without recourse to books in which information is imparted in a more diffuse manner.

Dr. Leffmann has so frequently shown that he is capable of proving the analyses of which he teaches, that we have full confidence in his work, and recommend this book to any members of the profession who are interested in such matters.

A Latin Grammar of Pharmacy and Medicine. By D. H. Robinson, Ph.D., and L. E. Sayre, Ph.G. Philadelphia: P. Blakiston, Son & Co., 1890.

The object of this useful book is a very laudable one, namely, to improve, if possible, the Latin used by both physicians and druggists, chiefly in the prescribing of drugs. While it is true that many of the profession find it unnecessary to remember the genitive endings of words used in medicine, because of the customary abbreviations in prescription-writing, there are others who frequently desire to write their directions to the druggist in Latin in order that the patient may not learn of facts about which it is often necessary for him to remain in ignorance. We hope that the book will prove a success, and by its general employment in both pharmaceutical and medical schools improve the knowledge of Latin in both professions.

Contribution a l'Étude des Psorospermoses Cutanées et de certaines Formes de Cancer.
Maladie de la Peau dite Maladie de Paget. By Louis Wickham. Paris: G. Masson, 1890.

This capital monograph is composed of three parts. The first is a clinical study based upon the literature of Paget's Disease of the Nipple, containing especially full quotations from American authors, and a series of previously-unpublished observations. The second part deals with the anatomico-pathological nature of the malady, and is rich in liberal extracts from published researches, containing as well a number of new cases and a report of the histological examinations. The reader is here introduced to the remarkable observations of Darier on the forms of psorospermiæ seen in this disease. The final section includes a well-digested account of the pathogenesis of the affection, and the conclusions are reached that this malady should be considered as a special disease of the superficial epithelium, consisting of various grades of cellular proliferation; that it is a chronic disorder of the skin, due to parasites of the order of psorospermiæ; and that these parasites seem to have a direct influence upon the future development of epithelioma.

If these facts are accepted, and as microscopical examination of the small crusts from the diseased nipple affords an excellent and rapid method of diagnosis depending upon either the presence or absence of the parasitic sporozoa, the author argues that the disease of Paget in the first two degrees of the lesion should be treated, not by radical extirpation, but by the application of anti-parasitic substances. The curability of the affection in the earlier periods of its existence is readily conceived from this theory of its pathogenesis. Full directions for treatment according to the rules formulated by Darier are given, with a complete list of the most serviceable applications. Two excellent chromo-lithographs of "this disease of the skin, called the disease of Paget," and a number of beautifully-executed plates illustrating its histology and the habitat of the psorospermiæ accompany the volume. This excellent research commends itself alike to pathologists, dermatologists, and practical surgeons.

Saunders' Question Compends: Essentials of Minor Surgery and Bandaging. With an Appendix on Venereal Diseases. Illustrated. By Edward Martin, M.D. Philadelphia: W. B. Saunders, 1890.

This is one of the best condensations of the subjects of which it treats that has been placed before the profession for a long time. Most of these books make the mistake of detailing at unnecessary length all the possible forms of bandages which can be applied to the human body, and leave the reader stranded upon a shore where he can find nothing that will aid him in clearing up his ideas for treatment. The cuts which are introduced, although numerous, are all of them appropriate. Most of our readers will be interested to learn that the chapter upon Genito-urinary Diseases, though necessarily short, is sufficiently complete to make them feel thoroughly acquainted with the most advanced views on the subject, after having read each sentence carefully.

The publisher has been unusually fortunate, we under-

stand, in most of the numbers of this series, and we shall be surprised if the twelfth volume does not meet with more than the success obtained by the others.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meetings, October 24, and November 7, 1890.

THE PRESIDENT, F. J. SHEPHERD, M.D., IN THE CHAIR.

DR. W. A. MOLSON showed the stomach of an old woman. The organ was pyriform, the size of the closed fist; its walls were half an inch thick, and its capacity only four ounces. Microscopical examination proved it to be carcinomatous. The physical signs during life were insufficient to base a diagnosis upon.

Dr. Molson also showed a man aged thirty years with ankylosis of the spinal vertebræ. His neck was curved forward, but his head moved freely on the axis. This condition had been developing for three years. The muscles of the back were not wasted, but were abnormally firm. In the absence of a history of venereal disease the possibility of malingering had arisen; under ether, however, the vertebræ from the axis to the sacrum were found immovable. The man had had a slight attack of inflammatory rheumatism three years previously.

DR. JAMES BELL showed specimens from a case of malignant disease of the tongue. The organ and the floor of the mouth had been removed by an incision under the chin. The man died of gangrene of the lungs forty days after the operation.

DR. WILLIAM GARDNER showed a specimen of tubal pregnancy the size of a hen's egg. The fœtus was not found, but the villi made the diagnosis positive. The patient was a married woman, twenty-six years of age. The rupture occurred when gestation had advanced about two months and a half. On opening the abdomen a large quantity of effused blood was found. The patient made a good recovery. This is the second case observed in the practice of Dr. Gurd, and the third operation by Dr. Gardner, two of which were successful.

Meeting of November 7, 1890.

DR. JOHNSTON showed, for Dr. Molson, specimens from a case of general syphilitic infection. The specimens were portions of the tibia and calvarium, showing much thickening and induration; a thickened plaque from the pharnyx; and a rectal ulcer. The patient, a man of sixty years, had had perityphlitis and diarrhœa for three years. A peculiarity of the case was that the rectum was on the right side of the pelvis.

DR. H. L. REDDY reported the case of a woman of twenty years, who died suddenly, after a few days' illness which did not seem dangerous. A small, sharply-defined ulcer was found in the posterior wall of the stomach. Two years ago she had been treated for symptoms pointing to gastric ulcer, but had apparently recovered, and subsequently gave birth to a child and acted as wet-nurse.

DR. F. R. ENGLAND showed a patient who had a pedunculated tumor the size of a goose-egg and resembling a scrotum, springing from the perineum. Examination after removal, he said, would alone disclose its real nature.

DR. R. L. MACDONNELL related the history of a remarkable case of enlargement of the liver. The patient was a married woman aged thirty years, who had had good health until five years ago, when, after the birth of her first child, she suffered from a prolonged purulent discharge from the genitals. She has had two other children, and two miscarriages. Syphilis cannot be excluded, her husband being depraved. She has never suffered from serious digestive disturbance, nor from hæmatemesis, diarrhœa, melæna, hæmorrhoids, ascites, or jaundice. There is no appearance of ill health. The abdomen and legs are not swollen, and there are no enlarged abdominal veins. External evidences of syphilis are wanting. The margin of the liver can be felt two inches below the umbilicus, the notch between the lobes being perceptible. There is no pain on palpation. The upper border of hepatic dulness is two inches above the nipple, thus the hepatic dulness in the nipple-line is *thirteen and a half inches*. The growth of the liver has been slow and imperceptible. Examination of the urine gave no evidence of disease. The case was considered one of waxy liver, remarkable for the huge size of the organ, the hepatic dulness exceeding that of any case recorded. The waxy liver moulds itself over organs and spreads in the direction of least resistance. A liver nearly as large as this is described by Murchison. The absence of albumin in the urine weakens the diagnosis, but cases are on record of amyloid livers with normal kidneys, and moreover, kidneys may undergo degenerative changes without giving rise to albuminuria.

DR. J. A. HUTCHINSON showed a phosphatic calculus the size of a Haricot bean, which had been removed from under the tongue of a man.

Officers for the ensuing term: *President*, F. J. Shepherd, M.D.; *Vice-Presidents*, A. Proudfoot, M.D., R. L. MacDonnell, M.D.; *Secretary*, J. G. McCarthy, M.D.; *Librarian*, F. W. Campbell, M.D.; *Council*, James Bell, M.D., James Stewart, M.D., G. E. Armstrong, M.D.

CORRESPONDENCE.

CHICAGO.

(*From our Special Correspondent.*)

AT the meeting of the Illinois State Board of Health, recently held in Chicago, Dr. John H. Rauch, Secretary, presented his quarterly report, which was full of interest, and from which we will give a few extracts:

The general health in Illinois has been very good, and no disease has been particularly prevalent. Outbreaks of diphtheria have occurred in the southern and other portions of the State, but where the disease spread it was mainly owing to municipal neglect in enforcing the rules and requirements of the Board.

Scarlet fever of a mild type has been prevalent at Quincy, Monarch, Sumner, Decatur, and other places. Typhoid fever has been reported near Urbana, Clayton, Carthage, and Centralia. The outbreak near Urbana was especially virulent, in a family of eleven, nine having

died. Dr. Rauch is satisfied that if the proper sanitary precautions had been promptly taken the mortality would not have been as great.

On September 11th four persons were poisoned at Macomb by eating custard. It was supposed that the vanilla flavoring-extract was the cause, but Professor Long made an analysis of the vanilla, and found nothing deleterious in it, and is of the opinion that the cases were ptomaïne-poisoning.

Dr. Rauch dwells upon the necessity of making diphtheria a quarantinable disease at the maritime ports. While returning to the United States on one of the most popular lines of ocean steamers he found that a death had occurred in the steerage from diphtheria, and no special precautions were taken to prevent the spread of the disease. From observations made on the steamer Dr. Rauch thinks that proper care is not taken in the inspection of immigrants with reference to vaccination.

Dr. Rauch's remarks upon the prevalence of cholera in Europe and Asia, and the probabilities of its reaching this country next year have already appeared in THE MEDICAL NEWS.

Relative to the Medical Practice Act he said that at no time since the organization of the Board has there been such a rush of medical men to Chicago as during the past three months. More than two-thirds of the certificates issued were to physicians who wished to practise in Chicago. And never before in the same length of time have so many professional frauds attempted to obtain a foothold in Chicago. It is evident that the increase of population and especially the coming World's Fair are the attractions. Eleven applicants were refused licenses because they had diplomas from schools not in good standing, because their professional records had been tarnished elsewhere, or because they could not comply with the requirements of the Board. The anxiety to settle in Chicago is also manifest in the incorporation of so-called medical companies, medical associations, and dispensaries, thus taking advantage of the lax laws and attempting to evade the Medical Practice Act.

It is undoubtedly the duty of the Board to do all it can, to protect not alone the citizens of Chicago from this class of frauds, but the visitors to the World's Fair as well.

During the quarter there were received in the Secretary's office 1775 written communications—exclusive of diplomas submitted for verification, affidavits, letters of recommendation, etc.—pertaining to 124 applications for certificates entitling to practise medicine, and twelve applications from midwives. There were issued ninety-seven certificates based on diplomas of medical colleges which conform to the standard of minimum requirements; ten to graduates who were required to supplement their diplomas by evidence of proficiency in the subjects or branches omitted by their respective colleges; and six duplicates upon proof of loss or destruction of the original. Eleven applications were rejected because of inability to comply with the law. Certificates were also issued to seven midwives and licentiates; to three upon examination. Two were rejected. One itinerant license fee of $100 was refused. Letters of inquiry have been more than usually numerous from medical colleges and from boards of medical examiners with regard to the status of medical colleges.

GANGRENOUS STOMATITIS.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of November 15, 1890, there is reported by Dr. W. P. McDonnald, of Hill City, Tenn., a case of cancrum oris, or gangrenous stomatitis. I wish to put on record a similar case.

On August 10, 1890, I was called to see Anna D., aged eight years, who for six weeks previously had been suffering from typhoid fever. When I saw her she had no fever, was very much emaciated, and had not strength enough to raise her head from the pillow. The contents of the bowels and bladder were passed involuntarily. There was a purple spot on the right cheek; the circumference was hard and the centre thin and soft. There was a very offensive discharge from an ulcer on the inside of the cheek. She had been allowed to scratch this ulcer, and no regard was paid to cleaning her face and hands. Her eyes were closed, and her mother told me that they had not been opened for ten days. I washed her face and gently separated her eyelids, to find that purulent ophthalmia had destroyed both eyes. I had little hope of her recovery, but put her on stimulants, nutritious diet, and anodynes, and used a mouth-wash composed of equal parts of "Listerine" and glycerin. On the following day the left cheek became involved, and the ulceration soon extended to the inferior maxillæ on both sides. She lost several teeth with pieces of the maxillary bone. Strange to say, the patient recovered in about three weeks, but she is totally blind, her face is disfigured, and her mouth is closed by a fibrous adhesion between the cheek and lower jaw on the right side. She feeds herself through an opening made by the loss of two or three teeth on the left side. When the adhesion is broken up or cut through, she will be able to open her mouth.

J. T. GRAHAM, M.D.

WYTHEVILLE, VA.

NEWS ITEMS.

AN ACT

To Regulate the Practice of Medicine and Surgery, to establish a State Board of Medical Examiners and Licensers, to define the powers and duties of such Board, the qualifications of applicants for license, the manner of licensing, and making an appropriation for said Board.

Whereas, The safety of the public is endangered by incompetent physicians and surgeons, and due regard for public health and the preservation of human life demands that none but competent and properly-qualified physicians and surgeons shall be allowed to practise their profession;

SECTION 1. Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania in General Assembly met, and it is hereby enacted by authority of the same, that within one month after the passage of this Act the Governor shall appoint a State Board of Medical Examiners and Licensers consisting of nine members, three to serve for one year, three for two years, and three for three years in the first instance, and thereafter annually the Governor shall appoint three

members to serve for three years in place of those whose terms then expire. The said persons so appointed shall be graduates of some legally-chartered college or university having the power to confer medical degrees, citizens of the United States and of this Commonwealth who shall have been in the active practice of medicine or surgery for a period of not less than ten years, but no two of whom shall be residents of the same county (and none of whom shall be members of the faculty or staff of any medical school or university). Each member of the said Board shall receive a certificate of appointment from the Governor, and shall file the same within twenty days with the Prothonotary of the Court of Common Pleas of the county in which said member is registered under existing law.

SEC. 2. The said Board shall be known by the name and style of the State Board of Medical Examiners and Licensers of the Commonwealth of Pennsylvania, and shall have a common seal, and may make and adopt all necessary rules and regulations and by-laws not inconsistent with the Constitution and laws of this Commonwealth, or of the United States, and shall have power to locate and maintain an office within this State for the transaction of business. Five members of the said Board shall constitute a quorum for the transaction of business.

SEC. 3. Every appointment to fill a vacancy or vacancies in the said Board shall be for the unexpired term, and the said vacancy or vacancies shall be filled by the Governor within sixty days after the notification of the same by the Board, and he shall have power to remove any member of said Board for criminal, scandalous, or dishonorable conduct.

SEC. 4. The said Board shall organize at Harrisburg within three months from the date of their appointment, and shall elect from its own number a President and Secretary who shall also act as Treasurer, both of whom shall hold their offices for one year, or until their successors are chosen.

SEC. 5. The members of the said Board shall each receive a salary not exceeding three hundred dollars per annum, to be paid out of the fees for examination. The Secretary and Treasurer shall receive an additional salary, to be fixed by the Board, and shall file with the President of the Board a bond in the sum of one thousand dollars, conditioned for the faithful performance of his duties. The necessary expenses of the said Board shall also be paid out of the fees, except as provided in Section 12 of this Act, and any balance remaining from the fees, after the disbursements herein specified, shall be paid into the treasury of the Commonwealth.

SEC. 6. The said Board shall examine all applicants for license to practise medicine or surgery in this Commonwealth who are properly qualified according to the provisions of Section 7 of this Act, and no one shall be excluded or rejected on account of adherence to any special system or school of practice. It shall hold two stated meetings in each year, one at Pittsburg and one at Philadelphia, respectively, and may hold special meetings at such times and places as it may deem proper. All examinations, when practicable, shall be conducted in writing, and all examination papers, together with the reports and action of the Examiners thereon, shall be preserved among the records of the said Board for a period of five years, during which time they shall remain open for inspection at the office of the said Board.

The applicants shall be examined in anatomy, physiology, chemistry, toxicology, pathology, hygiene, materia medica, and therapeutics, principles and practice of medicine, surgery, and obstetrics, and each applicant upon receiving from the Secretary of the Board an order for examination shall draw by lot a confidential number, which he or she shall place upon his or her examination paper, so that when said papers are passed upon by the Examiners the latter shall not know by what applicant said papers have been prepared, and upon each day of examination all candidates shall be given the same set of questions. Provided that any candidate for examination may elect the system of materia medica and therapeutics in which he or she shall be examined.

SEC. 7. Any person on paying twenty dollars to the Secretary of said Board, and on presenting satisfactory proof of being over twenty-one years of age, of good moral character, and of having received a sufficient preliminary education, as defined by said Board, and a diploma from some legally-incorporated medical college or university having authority to confer degrees in medicine, shall be entitled to examination by said Board, and in case of failure at any examination shall have the privilege of subsequent examinations without the payment of an additional fee. Each applicant who shall have passed a satisfactory examination shall receive from the said Board, under seal, a license to practise medicine and surgery in the Commonwealth of Pennsylvania, and the said Board may at its discretion grant licenses, without examination, to persons holding licenses from similarly-constituted boards of examiners or boards of health in other States.

SEC. 8. The Secretary shall record in a book to be kept for this purpose in the office of the said Board, the name, age, sex, residence, date, and place of examination, the examination number, the examination average on each branch, the general average, and the date of issue of license, in case such license is granted. Said book shall be open to public inspection, and on or before the last day of December of each year the said Board shall publish, or cause to be published, a list of the names and addresses of such persons as shall have received licenses from the said Board within twelve months immediately thereto preceding.

SEC. 9. After the first day of July, Anno Domini one thousand eight hundred and ninety-one, no person shall enter upon the practice of medicine or surgery in the State of Pennsylvania unless he or she has complied with the provisions of this Act, and shall have exhibited to the Prothonotary of the Court of Common Pleas of the county in which he or she desires to practise medicine or surgery, a license duly granted to him or her by the said State Board of Examiners and Licensers, whereupon he or she shall be entitled, upon payment of one dollar, to be duly registered in the office of the Prothonotary of the Court of Common Pleas in said county, and any person violating any of the provisions of this Act shall be guilty of a misdemeanor, and upon conviction thereof in the Court of Quarter Sessions of the county where the offence shall have been committed, shall pay a fine of not less than one hundred dollars nor more

than five hundred dollars for each offence, one-half of which fine shall be paid to the prosecutor.

SEC. 10. Nothing in this Act shall apply to commissioned medical officers of the United States Army or Navy, or of the United States Marin-eHospital Service, nor to any member of the house or resident staff of any legally-chartered medical college or university or hospital during his term of service therein, nor physicians of other States meeting duly registered physicians in this State in consultation, nor to those practising dentistry exclusively. And nothing in this Act shall be construed to prohibit the practice of medicine and surgery within this Commonwealth by any practitioner who shall have been duly registered before the first day of July, Anno Domini one thousand eight hundred and ninety-one, according to the terms of the Act entitled "An Act to provide for the registration of all practitioners in medicine and surgery," approved the eighth day of June, Anno Domini one thousand eight hundred and eighty-one.

SEC. 11. For the purpose of this Act, the words "practise medicine or surgery" shall mean to treat, operate on, or prescribe for any physical ailment of another. But nothing in this Act shall be construed to prohibit service in cases of emergency or the domestic administration of family remedies.

SEC. 12. The sum of one thousand dollars, or so much thereof as may be necessary, is hereby appropriated to meet the necessary and legitimate expenses of the said Board for the year Anno Domini one thousand eight hundred and ninety-one.

SEC. 13. All Acts or parts of Acts of Assembly inconsistent herewith shall be and are hereby repealed.

The Medical Society of the County of New York.—This Society has awarded a prize to Dr. David Cerna, of the University of Pennsylvania, amounting to $100, for his essay upon the "Physiological Action of Hydrastis Canadensis." The essay, we understand, is a very exhaustive and careful study of the subject of which it treats.

Chair of Otology in the University of Pennsylvania.—Dr. Burton Alexander Randall, a graduate of the University of Pennsylvania in 1880, has been appointed Clinical Professor of Otology in the University to succeed Dr. George Strawbridge, who resigned some months ago on account of ill health. Dr. Randall is well known in the profession, not only because of his skill in the treatment of affections of the ear, but also by reason of his careful pathological and anatomical work in connection with this portion of the body. An abstract of a very interesting paper upon "Corrosion Methods in Studies of the Ear" appeared in *The American Journal of the Medical Sciences* for January, 1891. Dr. Randall is also the author of a volume of photographs of the ear, which are extraordinary because of their skilful execution. In addition to a very wide clinical experience in this country, Dr. Randall has had ample opportunities of becoming well versed, in the subject which he is to teach, in European clinics, and we congratulate both the University and the appointee upon his accession to the professorship.

A Medical Directory.—Mr. George Keil, of 1715 Willington Street, Philadelphia, is about to publish a medical and dental register, directory and intelligencer of the States of Pennsylvania, New Jersey, and Delaware. This directory will be presented gratis to the members of the profession, the expense being paid by the advertising which it contains. It will also contain a list of the National State Medical and Dental Organizations, the names of officers, the office-hours of all doctors and dentists, with the school and year of their graduation.

A Dispensary for the Treatment of Diseases of Women by Electricity.—A dispensary for the treatment of the diseases of women amenable to electricity has been opened at 1632 Cherry St., Philadelphia, under the charge of Drs. G. Betton Massey and Horatio R. Bigelow. Physicians are invited to bring or send suitable cases on Mondays, Wednesdays, and Fridays at 3 P. M.

To Found a New College and Hospital.—The Brooklyn Post-Graduate College and Hospital has been incorporated with the following officers: President, Dr. George R. Fowler; Secretary, Dr. Reuben. These officers, with Drs. Glentworth, Butler, and Charles Jewett, will form the Governing Council. The Board of Managers consists of Drs. West, Van Cott, Fuhs, Lennox, Browning, Price, Dayton, and Pilcher, and Mr. Wensley. The institution will provide for instruction in all departments of medicine and surgery and a dispensary will be established. The site of the buildings is not yet determined.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 30, 1890, TO JANUARY 5, 1891.

By direction of the Secretary of War, the following-named medical officers will proceed, without delay, to Pine Ridge Agency, South Dakota, and report in person to the commanding general Department of the Platte, for duty in the field: HENRY S. KILBOURNE, *Captain and Assistant Surgeon;* EDWIN F. GARDNER, *Captain and Assistant Surgeon;* and EDWARD EVERTS, *Captain and Assistant Surgeon.*—Par. 9, *S. O. 304, A G. O.*, December 30, 1890.

By direction of the Secretary of War, JOHN V. LAUDERDALE, *Major and Surgeon*, now on duty at Fort Ontario, New York, will proceed, without delay, to Pine Ridge Agency, South Dakota, and report in person to Brigadier-General John Brooke, for duty in the field, and by letter to the commanding general Department of Dakota.—Par. 8, *S. O. 303, A. G. O., Washington, D. C.*, December 29, 1890.

By direction of the Secretary of War, the extension of leave of absence, on account of sickness, granted STEVENS G. COWDREY, *Major and Surgeon*, in Special Orders, No. 293, December 16, 1890, from this office, is still further extended one month, on account of sickness.—Par. 8, *S. O. 302, A. G. O., Washingcon, D. C.*, December 27, 1890.

By direction of the Secretary of War, OGDEN RAFFERTY, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Sam Houston, Texas, and will report in person to the commanding officer Camp Eagle Pass, Texas, for duty at that station, reporting by letter to the commanding general Department of Texas.—Par. 2, *S. O. 301, A. G. O.*, December 26, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 3, 1891.

PICKERELL, G. MCC., *Assistant Surgeon.*—Detached from the U. S. Receiving-ship "Minnesota," and wait orders.

MCCORMICK, A. M. D., *Assistant Surgeon.*—Ordered to the U. S. Receiving-ship "Minnesota," as Dr. Pickerell's relief.

ORIGINAL LECTURES.

ARTHRITIS DEFORMANS—CANCER OF THE LIVER.

Abstract of a
Clinical Lecture delivered at Bellevue Hospital.

BY ALFRED L. LOOMIS, M.D.,
VISITING PHYSICIAN.

GENTLEMEN: This man comes to us with a history of having been in good health until about one year ago, although for about four years past he has had wandering pains about the joints. He is a man of temperate habits, and has lived in a healthful region, but his work as a farmer and lumberman has involved some exposure to wet and inclement weather. For some time previously to very marked symptoms in his joints, he noticed creaking in them, and swelling around them at night, which disappeared before morning. His mother and brother were similarly affected. The small joints were apparently first involved, and you notice particularly that he says the disease began in the big toe, but that after a short time, the other joints became involved. He was able to continue his work until about one year ago, when he suffered from a very acute attack, in which all the joints became affected; and since that time he has been more or less crippled. I wish you to notice especially that the joints became involved *progressively*—in other words, a joint, after once becoming affected, did not get well, but became steadily worse, until finally there was complete loss of motion. At present, the wrist-joint, although somewhat swollen, is not very tender, and if I grasp it firmly and attempt to move it, there is very slight motion, and some crepitation. I want to impress upon you that one of the earliest and most constant symptoms is this crepitation in the joint, and it is highly important that you should recognize its significance, for it is only in the very early stages of this disease that we can hope to accomplish anything by treatment. During the past year, I have seen two or three persons who, after a general feeling of ill-health, without any distinct rheumatic manifestations, developed this creaking of the joints, which was followed by the characteristic changes in the joints which we find in this case.

Even at a very early period, medicines are powerless to check the progress of this disease, and hence the danger-signal should be promptly recognized, and the appropriate prophylactic measures adopted. This patient had four or five years of premonition, yet the warnings were disregarded, and his habits of life were not changed. The disease is often hereditary, and this man's family history is not at all exceptional. Arterial degeneration does not occur until very late, and in this respect the disease differs from gout. Some physicians speak of this disease as "rheumatic gout," but one might just as well speak of measly-scarlatina, for rheumatism and gout are two distinct forms of disease. Each may appear in the same individual, but not at the same time. The condition we are studying is more correctly designated as *arthritis deformans*. It does not always present the acute symptoms described by this patient, but such symptoms are often present. Cardiac complications are infrequent. As you look at this patient, he seems to be well-nourished, to have a good color, and, in brief, to be in a very good condition; yet he is suffering from an incurable disease, which, when it attacks a joint, pursues its course relentlessly until the joint is permanently destroyed, and there is ankylosis or partial dislocation. This man's knee-joint has not yet become ankylosed, but I can feel the cartilages slipping around in the joint, and the presence of muscular atrophy increases the apparent deformity. There is already distinct creaking in the temporo-maxillary articulations. In some cases the jaws becomes so firmly fixed that the patients have to be fed with a tube.

Now, what is to be done with this man? The most we can promise is, that we may be able to arrest the progress of the disease, if his circumstances will allow of his carrying out the proper course of treatment; although he must understand that he is crippled for life. If the disease is to be arrested at all, it is by an entire change in the processes of his nutrition. It is absolutely necessary that he should be placed in a warm, dry climate, below the frost-line, where he may live most of the time in the open air. His diet must consist largely of milk, and all stimulants except spirits must be avoided. A moderate indulgence in spirits seems beneficial. In conjunction with this line of treatment, arsenic and cod-liver oil are capable of giving marked relief, but by themselves they are useless. If several years ago, this man had gone to a warm climate, and had been provided with the best hygienic surroundings, it is probable that the disease would not have advanced, or, at any rate, to so great a degree. In almost every country town you will find similar cases, which have been treated as cases of ordinary rheumatism until the time for helping them has passed. Please remember that this disease is incurable; that the premonitory symptoms are general tenderness and occasional soreness of the joints, followed by crepitation of the joints on motion. The latter is always suggestive and may enable you to make an early diagnosis. Then is the time, when, by carrying out the mode of treatment which has just been outlined, you may prevent or arrest its development.

CANCER OF THE LIVER.

The next patient tells us that his present disease began after exposure to wet and cold four months ago. He first felt pain in the region of the stomach, then below it, and a few days later, after another exposure, he began to suffer from pain in the left side. which increased

when he lay upon that side. Five or six days later, there was pain on the right side, especially on deep inspiration. The pain is still present, and is increased by motion as well as by inspiration. You notice that while I am talking the pain has become so severe as to cause him to turn a little upon the side. There is also a slight cough, which he endeavors to suppress. He has had no serious illness except an attack of malarial fever about eight years ago. Ten years ago, he had some form of venereal disease, but he has had none of the usual symptoms of syphilis. He began to drink liquor at the age of twenty-two years, but has only occasionally been intoxicated. His children are healthy. During his present illness he has lost flesh rapidly. Examination of the urine shows the presence of albumin and of granular and hyaline casts. His pulse indicates arterial tension, and would lead me to suspect the presence of some forms of nephritis. The temperature in a single instance reached 103°, but generally ranges from 99° to 100°.

Inspection shows a general fulness of the abdomen, an almost entire absence of abdominal respiration, and an enlargement of the superficial veins. The abdominal walls are so tense that palpation can be only imperfectly performed, but there are evidently great tension and tenderness over the upper portion of the abdomen, while the lower portion is yielding and painless. Over the upper portion the sensation to the hand is that of a solid mass of great size, and apparently deeply seated. The edge of the mass feels rounded, and is smooth and not nodular. There is no friction-sound over the enlargement below the free border of the ribs, and on coughing no murmur is heard over the mass. There is dulness along the right nipple-line for more than twice the normal distance, and flatness on percussion below the fifth rib posteriorly. Crepitating pleural friction is heard over the entire posterior part of the chest, but is more marked on the right side. A few œdematous râles are audible, and above the line of dulness the respiratory murmur is distinct. The heart-sounds are normal. There is no œdema of the lower extremities.

A man who has emaciated so rapidly without very high fever has evidently some serious malady, and the great pain, as well as the expression of his countenance, confirms this opinion. In cases of fatty liver the edge of the organ is rounded; in waxy liver it is sharp and well defined. This man has had none of the constitutional symptoms of syphilis, and it would be hardly possible to have advanced visceral syphilis without previous well-marked secondary manifestations. Waxy liver is the most common degeneration caused by syphilis, but there is a form of cirrhosis with gummatous formations which develops after syphilis, and is very closely allied in its symptoms to that seen in alcoholics. This man has not been an excessive drinker, and has not the bronzed hue or the slight yellow tinge which usually accompanies cirrhosis of the liver. Again, cirrhosis of the liver is not often accompanied by a rise of temperature; on the contrary, it is more commonly associated with a subnormal temperature. If this man, then, has cirrhosis it is complicated by some other condition. Hypertrophy and cirrhosis of the liver might account for the enlargement, and an attendant perihepatitis might account for the pain and tenderness. Perihepatitis causes pain in very many conditions of hepatic enlargement. In this way, waxy liver might be accompanied by pain. In abscess of the liver the organ is enlarged and there is generally a point of maximum tenderness. It is accompanied by some fever, and sometimes by jaundice. Usually there is a history of a chill, and sometimes fluctuation is present. Traumatism frequently precedes it, or there may be a localized suppuration involving some portion of the intestinal tract which gives rise to circumscribed hepatitis. The more acute abscesses not infrequently are associated with dysentery. When the abscesses are of slow development, and are not accompanied by very acute symptoms, there may be no assignable cause. If the abscesses are large, as they must be if they exist in this case, the patient would in all probability suffer from chills.

Here, then, is a patient with localized peritonitis, pleurisy, nephritis, and an enlarged liver. The most important question, and the most difficult one to answer is, What has produced this enlargement of the liver? There is undoubtedly a perihepatitis, and an extension of the inflammation from the abdominal cavity through the diaphragm into the pleura. We cannot at present make a positive diagnosis in this case between abscess and cancer of the liver, but I am inclined to think that the disease is cancer.

KOCH'S METHOD OF TREATING TUBERCULOSIS.

A Lecture
delivered in the Jefferson Medical College,
January 8, 1891.

BY SAMUEL G DIXON, M.D.,
BACTERIOLOGIST TO THE ACADEMY OF NATURAL SCIENCES OF PHILADELPHIA.

GENTLEMEN: While in Berlin I had the opportunity of meeting many prominent men who were interested in Koch's discovery and of hearing their opinions concerning it. It may not be out of place, therefore, should I venture to state briefly my impressions regarding Koch's remedy. Here is a diagram on the right side of which you may possibly recognize stained tubercle bacilli in lung tissue, whereas on the left tubercle bacilli, double stained, are represented. When these minute single-celled microorganisms in full vitality enter the animal economy in sufficient number to overcome the army of animal cells whose function it is to devour all intruders, an active destruction of tissue is set up which is very difficult to overcome, unless recognized in its very incipiency. The tubercle bacillus is man's greatest enemy and tuberculosis has robbed more families of happiness than any other disease; but I am ashamed to say that there is not yet a well-endowed bacteriological laboratory in this city of nearly a million inhabitants. Studies such as those of Koch should stimulate rich men to endow laboratories for original research and teaching.

In 1889 I advanced the theory that by a thorough filtering out of tubercle bacilli from tubercular matter we might obtain a fluid which could be so weakened that by systematic inoculations a change might be produced in living animal tissue that would overcome tuberculosis. The announcement of this theory was accompanied by a statement that favorable results had been obtained

in animals so treated. Owing to an unavoidable delay I was unable to push my work to a close. I regret the interruption to my work, for during this time Professor Robert Koch, for whom I have the most profound respect, produced the fluid that I now hold in my hand, which probably contains less débris than any I had obtained at the time when he made his first announcement. About one one-thousandth dilution of this, it is supposed, acts upon tuberculous tissue.

The reagent is, probably, a metabolic product of the tubercle bacillus, the bacilli having been filtered out. With this active principle I am inclined to believe there are glycerin, gelatin, and some salt, probably a salt of gold. How this filtrate acts we do not know, but it may be conjectured that when the bacillus comes in contact with animal tissues it is stimulated to secrete some material which changes the chemical arrangement of the tissues and renders them capable of being absorbed.

The effect on the tissue seems to be an inflammatory one of a degree peculiar to the action of the tubercle bacillus and suited to its existence. If this be an explanation of the process, we may seek to neutralize the secretion of the bacillus and thereby prevent it from acting on the animal tissues; or again we may cultivate the organism on an artificial medium and then isolate in a concentrated form that which breaks up tuberculous tissue. This material when injected into the system which is already the habitat of the tubercle bacillus, meets with the normal secretion of that microorganism which is present in amounts just sufficient to render the tissues suitable for the growth of the bacillus. As soon as the artificial poison is added, the inflammatory condition of the tuberculous tissues becomes greater than that degree suited to the life of the existing microorganisms, the tissue is killed, and with the organisms falls away from the new surface. This is but a theory, for tuberculosis is a chronic disturbance, in which the microörganism is not killed by its own product as we suppose is the case in acute infectious diseases.

Dr. T. Lauder Brunton intimates that the Koch fluid may be a product of other than the tubercle bacillus. He cites the fact that lupus has been seen to shrivel and necrose after an attack of erysipelas or measles, and that peritonitis, supposed to be tubercular, has disappeared during recovery from diphtheria.

I believe that the Koch liquid is made from or by means of the tubercle bacillus. Its action on tuberculous tissue is simply marvellous. During my short stay in Berlin I did not see the reaction take place in tissues other than those which I suspected were tuberculous, unless it was in the nodules of leprosy. The lepra tubercles seemed to change color somewhat under the action of the Koch fluid. Yet to get the characteristic reaction, a dose sufficiently large to react on a healthy person had to be administered. If it does affect leprosy tissue, it is not surprising, as the lepra bacilli that I have examined appear to be related to the tubercle bacillus. However, their smaller size and their apparent motility being the points of difference, at present I am inclined to the opinion that the reaction produced by Koch's fluid is diagnostic of tubercular tissue; yet, until its curative power is determined, we must be cautious in our use of it as a diagnostic agent, for we have been taught that inflammation which, in all probability is tuberculous, is often set up in tissue that before treatment was apparently healthy.

The common experience with lupus-cases is somewhat as follows: In about five hours after the injection of the fluid, the temperature begins to rise, reaching its maximum quite suddenly. Then it soon falls to normal and in very anæmic patients reaches an alarmingly low degree. In one case of pernicious anæmia death soon followed the injection.

During treatment, a nodular infiltration takes place. The œdema which is present in many cases is exaggerated. As the fever subsides, prostration is often experienced, and the nodules gradually become covered with a crust under which can be detected healthy granulations. When these crusts fall off, red cicatrices are to be seen, and the surface soon presents the appearance of a perfect cure; but in some cases, after a few weeks the lupus-spots take on an inflammatory condition. We do not know how far the remedy destroys tuberculous tissue, for while it destroys recognizable tuberculous matter, the recurrence of the disease demonstrates that there may exist tuberculous tissue which the remedy will not destroy.

In the Charité Hospital I saw a case of lupus in a boy ten years old. The lesion began about the bridge of the nose and extended down on either side, involving the alæ and the skin covering both the superior and inferior maxillary regions. An injection of 0.002 gm. of Koch's fluid caused a rigor, vomiting, and a severe reaction, the temperature reaching 105° F., with the symptoms that usually follow the administration of a large dose when the area of tuberculous tissue is extensive. The patient soon became covered with a rash resembling scarlatina, and this process went on to desquamation, which involved the entire surface of the body. The lupus-tissue passed through the changes described until a healthy cicatrix was formed.

In another case of lupus, an irritating cough and harsh voice developed after the second injection. After the third injection, small clusters of red excrescences appeared on the right vocal cord. After some days the lupus was seen to be granulating nicely, the inflammation on the vocal cord had subsided, and the cough was rapidly decreasing.

To use the liquid, a one-per-cent. solution should be prepared by placing 0.1 c. c. of the fluid into a glass vessel graduated to 10 c. c. The vessel is then filled to 10 c. c. with sterilized water. 1 c. c. of this solution contains a dose of 0.01 c. c. of the original Koch fluid. The Koch syringe that I have here is graduated in tenths up to a capacity of 1 c. c.; therefore, if 1 c. c. of this one-per-cent. dilution be placed in the syringe, one-tenth of the syringeful will contain 0.001 c. c. of the remedy. In giving large doses, the ten-per-cent. dilution should be used.

Owing to the suppuration set up by the Koch liquid, in the vascular tissue immediately surrounding the tubercles, the remedy is positively contra-indicated in tubercular meningitis. This being so, the practitioner in treating other forms of the disease must be on the watch for indications of cerebral involvement.

Regarding its value in surgical tuberculosis, I can remember one case of resection of a rib of a patient in the Charité, in which the granulations had become

indolent, and the wound absolutely refused to heal until put under the Koch treatment. Reaction was produced by the first inoculation, after which healthy granulations developed and continued up to the day that I last saw the case, which was about the tenth day after the first injection.

The therapeutic value of the fluid in joint- and bone-tuberculosis is promising. Children in the Charité Hospital suffering with hip-joint tuberculosis seemed to experience much less pain when the joints were moved after treatment with the Koch lymph. The results in cases treated with the remedy until no further reaction could be produced and then operated on by mechanically removing all the necrosed bone and tissue seemed to be much better than those not so treated. If the necrotic parts are not removed they are likely to reinfect the system, as the débris disintegrates. This is especially so when there is a general predisposition to tuberculosis.

In one case of kidney-tuberculosis tubercle bacilli were found in the blood and urine. The remedy caused rigors and vomiting and an elevation of temperature to 105° F. When I last heard, this case was going from bad to worse.

After a successful experience with a reagent on guinea-pigs suffering from tuberculosis of the lung-tissue, I am disappointed that more has not been accomplished, but I have much faith in the ultimate triumph of the liquid over pulmonary phthisis, provided that the lesion is recognized and treated in its very incipiency. It must be borne in mind that the guinea-pigs which I have cured were in all probability not predisposed to tuberculosis. The remedy may render tissues more susceptible to the action of bacilli than before its introduction. Further, it may even disseminate bacilli into tissue that otherwise would never have become tuberculous. Should the dissemination of tuberculosis be extensive, the great decrease in the healthy lung parenchyma may prove disastrous to the life of the patient. Consequently, the remedy is positively contra-indicated in widely-disseminated lung tuberculosis, unless a much smaller dose than I have yet heard of be employed. My idea is, then, that we may be able to reduce the dose, so that it will be neutralized before it stimulates inflammation throughout the entire tuberculous tissue, and in this manner the living tuberculous tissue may be acted on step by step, so as not to cut the life of the patient short by a general inflammation throughout the entire area of tubercular tissue at one and the same time. What I have said about extensive lung tuberculosis, I believe will hold good regarding extensive tuberculosis of the larynx.

I cannot believe that a small cavity in the lung positively contra-indicates the use of the remedy. It is possible that the necrotic tissue will be absorbed and that the newly-formed walls in a number of cases will resist the attack of the living bacilli left in the necrosed tissue and cheesy masses.

In the treatment of mild cases of pulmonary tuberculosis, small doses of the liquid are used, the average initial dose being 0.001 c. c. About five or six hours after the injection there may or may not be a chill, followed by fever running from 102° F. to 106° F. The fever generally falls within two hours after it reaches its maximum, while sometimes it continues for forty-eight hours. The fever is not always in proportion to the size of the dose, so that at any time there may be an excessive rise after a prolonged period of moderate elevation. In one case the pulse increased to 160 and the respirations to 40. Diarrhœa is not an uncommon symptom. Enlargement of the spleen and the lymphatic glands is frequently perceptible. The patients often have an expression of great illness. The sputum frequently increases in quantity and contains necrosed tissue. The bacilli also increase in number after treatment, and you frequently find a change in the form of the bacilli resembling in morphology those we can cultivate on culture-media poor in peptones. After prolonged treatment both the sputum and bacilli decrease, while in many instances the tubercular process would seem to continue even after the injection of the liquid ceased to produce any reaction. The physical signs from percussion and palpation do not change except when an active inflammation is set up by the reagent, in what was not recognized as tubercle tissue.

To picture better the action of the remedy in pulmonary tuberculosis, I will give you the following history of an interesting case in the Charité:

A girl, aged twenty-three years, who had been treated with morphine and creasote. Her father and mother died from phthisis, and she has sisters now suffering from the same disease. Menses began at the age of eighteen and have been regular.

She was healthy before the summer of 1888.

Nine weeks ago when she entered the hospital her muscles were flabby and she felt weak, but there was no loss of power.

Conjunctiva, lips, and oral mucous membrane anæmic. Tongue moist. Teeth good. Pulse normal. Form of chest good. Costal respiration somewhat increased on both sides. Lungs and heart of normal size. Slight dulness over left apex, but still some vesicular breathing, with a few crepitant râles. Dry, hacking cough.

Weight on entering, one hundred pounds. In three weeks she lost two pounds.

Bad cough, difficult expectoration, and slight pain in apices and other parts of the chest. Could not eat well. Cough caused vomiting. Night-sweats.

When she entered the hospital she could not sleep even after the administration of one-fourth of a grain of morphine.

November 19. Over right apex vesicular breathing. Dulness over left apex. Between the arytenoid cartilages there were to be seen projections forming the walls of ulceration.

21st. 0.002 c.c. of the Koch fluid injected. Slight nausea. Temperature rose to 38.3°. Expectoration increased. Pulse 100. Respirations 20.

22d. 0.005 c.c. of the Koch fluid injected. Morning temperature normal. At 6 P. M. 39.8° C. Pulse 124. Respirations 25. Spots on larynx slightly swollen. Cough looser.

23d. Morning temperature normal. Evening temperture 37.6° C. Respiration 22, pulse 104. Gray spots appear on larynx.

24th. 0.005 c. c. injected. Morning temperature normal. At 6 P. M. 38.6° C. Slight friction-sound in left lung between axillary and mammary lines. Marked enlargement of the ulcers on the arytenoid cartilages. Left vocal cord shows grayish spots; moist râles in left apex.

Increased dulness in left lung. Further enlargement of ulcers on arytenoid bodies. Bronchial breathing. Great weakness.

26th. 0.008 c. c. injected. Morning temperature normal. Evening temperature, 9 P. M., 40.1° C. Pulse and respiration unchanged. Cough increased. Expectoration lessened. Sleeplessness returned.

27th. No change.

28th. 0.010 c. c. injected. Afternoon temperature, 38.3° C.

29th. A markedly improved general condition. Area of dulness lessened. No râles to be heard excepting over right clavicle.

December 1. 0.013 c. c. injected. Afternoon temperature 38.8° C. Up to this time there was a gain in body-weight of two pounds.

4th. 0.015 c. c. injected. Afternoon temperature, 39.5° C. Pulse 130. Respirations unchanged. Area of dulness increased. An increase of râles. With these conditions, a general disturbance was manifest. Bacilli continue in as large numbers as at first.

8th. The patient has lost one pound.

This history is about an average one. It certainly teaches us very little excepting that if improvement in pulmonary phthisis occurs under the Koch treatment, it is exceedingly slow, yet at the same time it shows that there is little or no *immediate* danger in the use of the liquid in mild cases of pulmonary tuberculosis, unless in exceptional cases in which there happens to be tissue that is hypersensitive to the action of the remedy.

While watching the effects of the liquid on lupus, the question that arises is, After the treatment, what condition are the tissues in immediately adjoining those which were sufficiently tuberculous to necrose under the inflammatory process produced by the Koch fluid? Will this apparently healthy tissue in the human economy be rendered immune, or will it be rendered more susceptible to the tuberculous process?

Professor Koch personally informed me that he felt quite certain of the power of his remedy to cure lupus and very mild cases of laryngeal tuberculosis, but that he did not believe it safe at present to make any estimate of its therapeutic value in other forms of tuberculosis.

A CASE IN WHICH A FOREIGN BODY WAS LEFT IN THE ABDOMINAL CAVITY AFTER OVARIOTOMY;

And Some Remarks upon the Effect of Tapping a Unilocular Ovarian Cyst.

BY RICHARD WILSON, M.D.,
OF PHILADELPHIA.

THROUGH the kindness of Dr. Walter F. Atlee, I am permitted to publish the following case, which is of interest on account of the rare and serious accident which happened, and because it shows once more the effects of tapping on the contents of an ovarian cyst.

Mrs. T. P., aged fifty-one years, married, has three children, the youngest eleven years old. She ceased menstruating about six years previously to the time when first seen by Dr. Atlee, January 19, 1888. For many months she had been treated medicinally for "abdominal dropsy." Dr. Atlee diagnosed a monolocular ovarian cyst, and the patient refusing ovariotomy was tapped. The liquid flowed freely through the tube to the amount of three gallons (one and a half bucketfuls), and was readily recognized as the contents of a cyst.

April 22, 1889. The patient, who again refused to have the cyst removed, was tapped a second time. One gallon of glutinous fluid, which was so thick as to flow with difficulty through the large tube, and colored with blood, escaped.

July 29. Ovariotomy was performed by Dr. Atlee, with two assistants besides the anæsthetizer. There was much ascitic fluid in the abdomen; the contents of the tumor were gelatinous and would not flow through the canula, although a large one was used. The pedicle was dropped into the abdomen.

Before the operation, the assistant who had charge of the sponges forgot to count them, and after the operation he found eight. Dr. Atlee said that he always used nine sponges, and ordered the room to be searched for the missing sponge—a flat one the size of a hand, introduced to absorb the blood while suturing the abdominal walls. As he was in a hurry, having a pressing engagement, he did not wait, so confident was he that the sponge would be found. But it was not found.

The patient did perfectly well until August 2d, the fourth day after the operation, when nausea and vomiting, with tenderness and swelling of the abdomen developed. Dr. Atlee thought that he felt to the right of, and somewhat above, the navel, a body that might be the missing sponge. On the next day he made an incision one and a half inches to the right of the umbilicus, cut through the rectus muscle, and found the peritoneum very much thickened. On opening the peritoneum very foul, stinking gas and some fluid escaped. The sponge was found adherent to the abdominal parietes and to the intestines. The adhesions were torn with the fingers, and after the sponge was removed the intestines had the appearance of coarse velvet. The patient died at 10 P. M. of the same day.

This case is interesting for two reasons. In the first place, there have been very few cases in which foreign bodies were left in the abdomen, and most of these have not been published. Dr. H. C. P. Wilson,[1] of Baltimore, who published a detailed account of a case that happened in his practice, was able to collect the reports of thirty other cases. Of these only ten cases had been published.

In commenting upon this subject, Dr. Wilson says:

"I am convinced that this is a much more frequent cause of death than any of us suppose, and if we were able to collect the number of fatal cases resulting from this source we would be surprised. Unfortunately,

[1] Foreign Bodies Left in the Abdomen after Laparotomy. Transactions of the American Gynecological Society, vol. ix. pp. 94–108.

many of the known fatal cases are not published, because they are damaging to the surgeon's reputation in the profession and in the community in which he lives. Hence these cases are rarely given to the world."

In looking through the *Index Medicus*, I have been able to find the report of only one case in which this accident happened, since the publication of Dr. Wilson's case. This was reported by Dr. W. Gill Wylie,[1] in whose practice it happened, and is in a "Table of Sixteen Miscellaneous Laparotomies" (Table IV., Case 3). The case is as follows:

A married woman, aged thirty-two years, with one child. A diagnosis of abdominal pregnancy had been made. The fœtus was killed at seven and a half months, and there were septic symptoms for several weeks. Abdominal section was performed February 10, 1887. The patient was weak from the prolonged sepsis, and her abdomen was greatly distended. The fœtus, placenta, and several quarts of decomposing fluid were removed. A drainage-tube was used after the operation. The patient "died in thirty-six hours from shock and sepsis." There was "no loss of blood during the operation. Sponges left in the cavity by mistake."

Dr. Wylie makes no further comment on the case.

I think that undoubtedly other cases have occurred since 1884, but either they have not been published, or, like the case of Dr. Wylie, were published among others in tabular form, the title of the article not calling attention to tne case. I have looked through several of such tables without success.

The following is a *résumé* of the thirty cases collected by Dr. H. C. P. Wilson. My excuses for quoting them are the rarity of the accident, its importance, the fact that it has occurred in the practice of skilful surgeons, and that it has been insufficiently noticed, and in the hope of causing greater care in counting the sponges during an abdominal section.

CASE I.—The surgeon was closing the abdomen when his assistant reminded him that there was a sponge in the cavity.

CASE II.—All the stitches had been inserted, and the surgeon was closing the wound, when an assistant told him that a sponge was missing. The wound was opened and after some time the sponge was found behind the intestines.

CASE III.—A sponge was missing after the abdomen had been closed. The wound was opened and the sponge removed. Patient recovered.

CASE IV.—The absence of the sponge was not discovered until revealed by a post-mortem examination.

CASE V.—An autopsy revealed a pair of forceps in the abdominal cavity.

[1] "A Year's Work in Abdominal Surgery, with Report of Eighty Laparotomies done in 1887." Transactions of the Medical Society of the State of New York; Syracuse, 1888, pp. 242–259.

CASE VI.—Dr. H. C. P. Wilson's case. The presence of the sponge in the abdomen was not suspected until it worked its way to the surface several months after the operation, and was removed by Dr. George H. Hocking. The patient recovered.

In commenting on this case Dr. Wilson says:

"This case, so far as I am aware, is unparalleled in the history of abdominal surgery. A woman, five months advanced in pregnancy, has an ovarian tumor removed from her, has a large piece of sponge left in the abdominal cavity, miscarries eighteen days after the ovariotomy, has the sponge remain in her body five months and eighteen days before it escapes through the abdominal walls, and yet the woman is now living and in better health than ever before.

"By what accident this sponge was allowed to remain in the abdominal cavity, I do not know. Before closing the wound I ordered the sponges to be counted, which was done, and reported all correct."

Either a piece of sponge was torn off and permitted to remain, or the counting was incorrect.

The foregoing six cases occurred in America, the following fifteen in Europe. Ten European cases are unpublished (Cases VII. to XVI.), and Wilson could get no history of them, but publishes them on the authority of Lawson Tait, who, after describing his own fatal case, says: "I happen to have heard of ten other cases in which the sponge was left behind.

CASE XVII.—Lawson Tait describes his case as follows: "In one of my operations, a bystander, hearing me ask for a small sponge, tore one in two, so that there were thirteen sponges in use, instead of twelve, and both the nurse and myself were ignorant of the fact. The gentleman who tore the sponge alone knew of his act, and he left the room before the operation was finished. The result was, that we found the thirteenth sponge four days after."

CASE XVIII.—A case of Spencer Wells's. While finishing an operation, Mr. Wells was told by an assistant that a sponge was missing. He requested the nurse to count them, which she did, and reported that they were all there. At the same time he felt in the abdominal cavity but did not find the sponge. This was at 2 or 3 o'clock P. M. At 8 or 9 o'clock P. M. his assistant reported to him that one sponge was missing, and that it must be in the patient's abdomen. At first Mr. Wells did not know what to do about it. As the patient seemed to be in good condition, he did not like to open the abdominal cavity again, so he decided to wait. In the morning the patient was very ill. "I took out two stitches and put my finger in; I felt the sponge, I took it out, reclosed the wound, and the patient was not much the worse for it."

CASE XIX.—Also happened to Spencer Wells, while removing both ovaries. He thought that he had removed every pair of torsion-forceps and closed the wound. About two hours after the operation, he received a message saying that a pair of forceps was missing and that probably they were in the patient's abdomen. The operator saw the pa-

tient at once. She was doing well, and he did not disturb her. She was very restless during the night. On the following day he examined her carefully through the vagina, rectum, and abdominal walls, but could not feel the forceps. Mr. Wells felt very uneasy, and decided to open the wound. Under the pretence of changing the dressing and that it would hurt her, he anæsthetized the patient with methylene, took out two stitches, inserted two fingers in the wound, and found the forceps wrapped in the omentum. From the way in which the omentum had insinuated itself into the ring-handles of the forceps and between the blades, it is easy to understand how difficult it was to remove the instrument; "but I did it, returned the omentum, and closed the wound, and the patient was none the worse. She got perfectly well, and, to this day, does not know that anything unusual occurred."

CASE XX.—A case of Dr. Carl Braun, in which a post-mortem examination revealed a sponge in the abdomen.

CASE XXI.—A case of Dr. Gustav Braun, in which a post-mortem examination revealed a pair of bull-dog forceps in the abdomen.

CASE XXII.—Reported by Dr. T. Gaillard Thomas. In an exploratory incision, a malignant tumor being found, one sponge only was used. The patient died in a few days, and a post-mortem examination revealed in the abdomen a piece of sponge, which must have been torn off.

CASE XXIII.—Reported by Dr. George J. Engelmann, of St. Louis. A post-mortem examination, after ovariotomy, showed a sponge in the abdomen. It was left there through the meddlesomeness of an assistant, which even the watchfulness of a careful operator could not restrain.

CASES XXIV., XXV., XXVI.—Reported by Dr. A. Reeves Jackson, of Chicago. In two cases a sponge was found in the abdominal cavity after death; in the third case a pair of hæmostatic forceps were found. As the gentlemen in whose hands these accidents occurred had not published them, their names were not given.

CASE XXVII.—Reported by Dr. William T. Howard, of Baltimore, as occurring in the hands of an English operator. A post-mortem examination revealed a sponge in the abdomen.

CASE XXVIII.—This case occurred in the practice of one of the most eminent surgeons of America, but as he never published it, his name is not mentioned. A sponge was found in the abdominal cavity.

CASE XXIX.—This case and Case XXX. Wilson reports in a foot-note, as he heard of them after finishing his article. Dr. Wilson received a letter from Dr. Walter F. Atlee, saying: "I was in Lancaster last winter (1883–1884), at my father's, Dr. John L. Atlee, when he received a letter containing the news of the death of a patient from lockjaw, from whom he had successfully removed a large ovarian tumor. When the body was opened, half a sponge was found in the abdomen, and it was discovered that one of the assistants had divided a sponge during the operation. When the sponges were counted after the operation the number was reported correct, and my father was satisfied. This is the last case upon which he operated before his health broke down, and it may have had something to do with his stroke."

CASE XXX.—Reported by Dr. William Wotkyns Seymour, of Troy, N. Y. The case was one of Dr. Horwitz's, of Copenhagen, in which a sponge in the abdomen was found to be the cause of death after abdominal section.

The second point of interest in the case I have reported is that it shows the bad effects of tapping in some cases. At the first tapping, June 18, 1888, clear liquid flowed freely through the tube. At the second tapping, April 22, 1889, the fluid was glutinous and very thick. At the operation, July 29, 1889, the contents of the tumor were gelatinous, and would not flow through a large canula.

All gynecologists are now agreed that, as a rule, ovarian and parovarian cysts should not be tapped. Tapping should be regarded as palliative only, says Emmet, and should not be resorted to except to make a diagnosis, or to gain time, when the condition of the patient does not admit of an operation. It is applicable to single cysts only, and should never be employed in the multilocular variety.

Tait says:

"I cannot regard the introduction of the trocar into the inflamed tissues of the pelvis as a procedure free from danger under all circumstances."

Spencer Wells,[1] from his first five hundred cases, concludes that

"It may be taken as almost certain that the mortality of ovariotomy is but little affected by tapping, that the fact of a patient not having been tapped, or having been tapped very often, is by itself of little or no value in prognosis. I have stated elsewhere that such adhesions as are apt to follow tapping have no appreciable effect upon the mortality after ovariotomy; and I can now add that in some of the patients who have been tapped most frequently there were no adhesions, and that there were firm adhesions in some who had never been tapped.

"Enough has assuredly been adduced to warrant the acceptance of the following propositions:

"(1) That one or more tappings do not greatly increase the mortality of ovariotomy.

"(2) That tapping may often be a useful prelude to ovariotomy, either as a means of gaining time for the patient's general health to recover, or of lessening shock, by relieving her of the fluid a few hours or days before removing the solid portions of an ovarian cyst."

The chief objections to tapping are: (1) The danger of peritonitis, should the fluid be irritating, as it often is, when even a few drops entering the peritoneal cavity might excite inflammation. This is more to be dreaded in the first tapping than in subsequent ones; for, if peritonitis does not set in after the first tapping, the fluid is unirritating, or the cyst is adherent to the abdominal walls. (2) There is always danger of the trocar puncturing a blood-vessel, in either the abdominal wall, the peritoneum,

[1] Diseases of the Ovaries, London, 1872, p. 275.

or the cyst itself. This is a most serious complication if the vessel is large, the symptoms being urgent for an immediate abdominal section. The accident, however, is not common, and the risk is reduced by tapping through the linea alba, which being tendinous, has few and small bloodvessels. (3) Adhesions are apt to form after tapping. These would complicate ovariotomy, should it be required later. (4) A cyst that has been tapped is apt to refill, necessitating a repetition of the tapping. This secretion and elimination of the fluid is a drain on the system (Goodell). On the other hand, Emmet says that, in many cases, tapping may be resorted to for years before the strength of the patient succumbs to the continued drain. Occasionally a single cyst does not refill after having been tapped; but if it does not, the probabilities are that the tumor is a cyst of the broad ligament, the fluid of which is bland and unirritating to the peritoneum. (5) If the cyst is multilocular and the largest cavity is tapped, by removing the pressure on the smaller cysts, it will give them a better opportunity to grow. (6) A cyst that has been emptied is apt to rotate on its axis, and torsion of the pedicle may result, ending in gangrene and peritonitis. (7) Repeated tappings tend to convert benign papillary growths into malignant growths (Goodell). (8) According to Tait, repeated tappings deprive the blood of some of its elements. Such elements are found among the great variety of albuminous substances in ovarian cysts, the deficiency of which in the blood predisposes to coagulation.

There are, however, cases in which tapping cannot be dispensed with: (1) Women often refuse the radical treatment, as they have heard of cases in which tapping was followed by cure. They will not submit to ovariotomy until repeated tappings have proved to them that this treatment is only palliative. (2) Cysts of the parovarium and of the broad ligament being often cured by the use of the trocar, it is proper to try the effect of one tapping in slowly-growing, unilocular, thin-walled, flaccid cysts, which thus exhibit the chief characteristics of these extra-ovarian cysts (Goodell). The contents of these cysts are generally limpid, but they may be very thick and gelatinous, and the color may vary from the lightest to the darkest shades. "When the contents are limpid and of low specific gravity, tapping probably does little harm to the constitution, for the system is robbed of little more than water. Such cases probably yield the instances in which tapping has been performed an enormous number of times over a long series of years" (Tait[1]). (3) In advanced pregnancy, tapping may be necessary to allow the woman to go to term. (4) If the cyst, by its large size, presses on the vital organs, and thus interferes with their functions. (5) To clear up a doubtful diagnosis. (6) In cases in which a large number of adhesions make ovariotomy impracticable.

FOREIGN BODIES IN THE NOSE IN CHILDREN, VERSUS NASAL CATARRH.

BY SAMUEL JOHNSTON, M D.,
SURGEON TO THE BALTIMORE EYE, EAR, AND THROAT CHARITY HOSPITAL.

AT first thought, it may seem impossible to mistake a foreign body in the nose for catarrh, and, doubtless, this is quite true if the patient is seen shortly after the accident. In many cases, however, when advice is sought, no history of a foreign body having been introduced into the nose can be obtained, and the attendant, therefore, treats the patient for simple catarrh, and, perhaps, only after months or even years have elapsed is the real nature of the affection discovered.

The frequency with which I have met instances of foreign bodies in the nasal passages being mistaken for catarrh leads me to believe that this error in diagnosis is not uncommon, and warrants me in briefly recording some examples in illustration of my observation. During the past few years five cases have come under my care in hospital and private practice in which this oversight had been made.

CASE I.—The patient had been the subject of so-called catarrh for one year, and had been treated for a variety of affections, among them malarial fever and inflammation of the brain. I removed a shoe-button from the right nasal fossa.

CASE II.—The patient was brought to my clinic with an offensive discharge, from one nostril, of several months' duration. A cinder the size of a small pea was found to be the exciting cause of the trouble.

CASE III.—This case had all the objective symptoms of chronic purulent rhinitis, chiefly affecting one side. The upper lip was excoriated, and the breath very fœtid. Upon exploring with a probe, a hard substance was detected, which, when extracted, was found to be an ordinary shoe-button.

CASE IV.—This patient was brought to me because the parents thought that the child had a tumor in her nose; and, judging from appearances, the diagnosis was not unreasonable. Protruding from the nasal orifice on the left side a fungous mass was observed, from which exuded a yellowish discharge tinged with blood. The face was slightly swollen, and the integument discolored on the corresponding side. A grating sensation was communicated to the hand upon the introduction of the probe, and further investigation, with the patient under ether, proved the obstacle to be a shoe-button.

CASE V.—A little girl from an adjoining State, had been treated for catarrh by her family physician

for two years, without success. Patent medicines had also been liberally used. The symptoms being those of a foreign body in the nose, I gave the child ether and removed a shoe-button from the right nasal fossa.

In not one of these cases had the nasal passages been properly examined. There is no better light than the sun for investigating the upper air-passages, and the simple introduction of a probe into the nostrils, the head of the child being held firmly between the knees of the surgeon, is not a difficult operation. If, on account of the restlessness of the child, this is not possible, a few whiffs of an anæsthetic will be sufficient to enable one to decide whether there is any obstruction in the nasal fossæ, and, if one is present, its nature. The diagnosis may also be made by a thorough examination of the nose anteriorly and posteriorly, and by ascertaining if the patient has at any time breathed perfectly through both nostrils, and if the coryza came on suddenly with a watery discharge and obstruction on one side.

Necrosis being excluded, a foreign body in the nose is the most rational diagnosis to make when we detect a hard substance in the nasal passages of a child. The age of the patient will also throw some light upon the case, for foreign bodies are most frequently found in children between the time when they begin to creep and the age of six years.

Foreign bodies in the nose may be mistaken for tumors, deviation of the septum, hypertrophy of the middle and inferior turbinated bodies, abscess, congenital syphilis, etc.; but these affections are excluded by careful examination.

Before beginning the operation for the removal of a foreign body from the nose, it is best to wrap the child in a sheet or towel, in order to confine the arms and legs; then, with an assistant holding the body, the head of the child is placed between the knees of the surgeon and a probe gently introduced into the nostril. If a foreign body is present, a sense of resistance will be felt if the substance be soft, or a grating sensation if it be hard, and the operation may be completed without delay. The parts surrounding the foreign body will, as a rule, be found swollen, and, for the purpose of reducing this turgescence, the application of a solution of cocaine is advisable, followed a few moments later by a spray of liquid alboline to facilitate the removal. The subsequent treatment consists simply in washing out the nose twice daily with a weak solution of the permanganate of potassium.

Of the various instruments for the removal of foreign bodies from the nose, I prefer Gross's extractor and the wire-loop in ordinary cases. A pair of slender forceps may be at hand for withdrawing the substance after it is brought to the nasal orifice. In children who are tractable the operation may be performed without an anæsthetic, but in the majority of cases much time and pain are saved by the careful use of an anæsthetic.

204 WEST MONUMENT STREET.

CEREBRAL SYPHILIS, WITH REPORTS OF CASES.[1]

BY FRANK P. NORBURY, M.D.,
ASSISTANT PHYSICIAN TO THE ILLINOIS CENTRAL HOSPITAL FOR THE INSANE, JACKSONVILLE, ILL.

AN essay might well be written on the consequence of syphilis to the human race, showing the baneful influence which this disease has been and is exerting upon the civilized countries of the world. Although its virulence, as the history of these countries shows,[2] is not now so malignant as it was in the past, yet much of the diseased condition of humanity is attributable to the inherited or acquired poison of syphilis.

I have not the time or the ability for such an essay, and shall confine my remarks to the effects of the disease upon the brain. The past twenty years have witnessed enormous strides toward establishing the principles of cerebral localization. There are yet many unexplained clinical facts regarding the seat of disease, but such facts as we now have enable us to understand more fully the functions of the brain, and the methods of diagnosis of cerebral disease. In cerebral syphilis the diagnosis depends in many cases wholly upon our knowledge of cerebral localization. The external evidences of the disease are wanting. The previous histories of such cases are, as a rule, defective, and the patient may be entirely ignorant of having had syphilis, because of the absence of the signs or symptoms of its primary or secondary stages.[3] Further, it is a fact, that nervous involvement due to syphilis generally occurs years after the appearance of the initial lesion, when the apparent evidences of the diathesis may have entirely disappeared, especially because the nervous system is more prone to be attacked when the secondary symptoms have been slight than when the earlier manifestations have been severe.[4] A great many cases have such marked constitutional symptoms that the presence of syphilis cannot be mistaken. The various cutaneous and osseous lesions themselves tell the tale which the patient will not. But, those obscure cases, with no cicatrices on the genitals or groins, no scars on the forehead, no tenderness over the sternum, and no iritic adhesions, are the cases which call for our recogni-

[1] Read at the Sixteenth Annual Meeting of the Mississippi Valley Medical Association, October 10, 1890.
[2] Medical Record, June 8, 1889.
[3] Dowse: Brain, vol. 1.
[4] H. C. Wood: Pepper's System of Medicine.

tion of the focal symptoms and their meaning. To diagnose cerebral syphilis we must keep in mind the propositions of Hughlings Jackson,[1] namely: (1) no single symptom is diagnostic of syphilis; (2) disorderly groupings and succession of certain symptoms are very strong evidence in favor of it; (3) certain single symptoms, however, are premonitory to the outbreak of more severe cerebral disturbances. Of these, headache, generally localized and with nocturnal exacerbations, is the most pronounced. Next, we may mention insomnia, which, says Buzzard,[2] when prolonged without any evident cause, should suggest an inquiry in regard to the existence of constitutional syphilis. Somnolence, also quite marked in many cases, and often terminating in fatal coma, is the first evidence of any cerebral disturbance. Vertigo, numbness of the extremities, loss of memory, excitability, and irritability of temper, are also premonitory symptoms.

Nearly all cases of cerebral syphilis are tertiary phenomena, and consequently due to gummata; but, in the observation of thirty-six cases of the disease I have seen several which were undoubtedly primary, and some which were secondary in origin.

The following cases of mental disturbance occurred during the continuance of primary symptoms:

CASE I.—A man, aged twenty-one years, who contracted syphilis three months previously. A phagedænic ulcer had formed, and was not quite healed when I first saw him. There was general enlargement of the glands, mucous patches in the mouth, and a pustular inflammation on the forehead. He was then under treatment for syphilis, and had been for some time, so that the manifestations of the disease were modified by the mercury he was taking. The cerebral symptoms were, briefly: Insomnia, headache, followed by somnolence, and later by a somnambulistic state. The last condition was first noticed while attending a party. He had an attack of severe headache, with vertigo, asked permission to lie down, was shown a bedroom, and his recollection ends with his lying upon the bed. He reappeared in the dining room after a short absence, and, much to the astonishment of all, was quite devoted to a young lady with whom it was known he had previously quarrelled. She could not account for his devotion, excepting by the belief that he had been drinking. His friends, fearing that such was the case, invited him to remain all night. In the morning, when told of his reappearance on the floor, and his attention to the young lady, he denied all recollection of it whatever, and accused his friends of joking. He further denied taking liquor of any kind.

Ten days later a similar attack, with the same prodromes, occurred. On this occasion he left home, and when he regained consciousness found himself in a hotel, in a city forty miles distant. How he came there, how long he had been away from home, or what he had been doing, he knew not. He returned home, and a few days later repeated the trip. This time it was forty-eight hours before he regained consciousness. As before, he had no recollection of what occurred. A third time he started for the neighboring city, but was overtaken by his brother at the railroad station. When accosted by his brother he appeared natural in his behavior, but was not subject to external influences, was seemingly in deep thought, was more or less automatic in his movements, and would not converse. When he regained consciousness he was greatly surprised to learn what he had done.

I saw him on the next day, when he was worried, melancholic, and self-accusative. After satisfying myself that it was undoubtedly a case of syphilis, I put him upon the iodide of potassium, and also directed him to continue the mercury. About three weeks later he reported again, saying that he had not been troubled since he first saw me, excepting with headache, lasting for a short time. He informed me that he contemplated going to Hot Springs, Arkansas, and this was the last time that I saw him. I have since learned that he returned home in due time very much benefited, and is now in a normal mental condition.

The strangeness of the symptoms, the departure from the ordinary type of organic disease, and the somnambulistic manifestation, all point to some perversion of the circulation, or an abnormal condition of the blood itself, affecting the supreme cerebral centres. If the cause was perverted circulation, we do not know the actual condition of the brain under these circumstances. It is reasonable to conjecture that alteration in the cerebral circulation was the cause, when we consider the distribution of the arteries and the physiology of sleep.

The arteries which supply certain areas of the convolutions may be affected, causing activity of the circulation in these vascular areas, and, as a result, somnambulistic dreams.[1] The affection of the arteries may be either vasomotor disturbance, or cell-proliferation within the walls of the vessel of the pia, causing diminution of the circulation, and, consequently, malnutrition, and lessening, or perversion of the functional activity of the ganglionic cells in the underlying brain-substance. If such is the case, the observation of and comparison with other cases might lead to localization of the mental faculties.

CASE II. *Late secondary phenomena.*—A man, aged twenty-three years, single (history defective). For six months prior to his admission in the Illinois Central Hospital for the Insane he was confined to his bed at home. When admitted he was feeble and emaciated, his circulation was poor, and bowels

[1] Lancet, February 21, 1880.

[2] Lancet, 1873.

[1] Maudsley: Physiology of the Brain.

constipated. The mental symptoms were those of acute primary dementia. He had not spoken for several months, stared vacantly, and, apparently, was not conscious of his surroundings. He was filthy in his habits, had an inordinate appetite, and would eat anything, including his own fæces. No history of syphilis was given by his friends, but evidences of primary lesions were marked. Secondary manifestations, such as thinning of the hair of the scalp, and skin eruptions, resembling psoriasis, on the posterior surfaces of the lower extremities and on the anterior surface of his arms, were present. (Hutchinson regards such an eruption as syphilitic in origin.) No marked superficial tertiary symptoms were shown.

Acting on the supposition that the case was one of syphilis, I immediately put him on anti-syphilitic treatment. No marked change occurred for several weeks, except a gradual improvement in his general health. At the end of three months he had improved so much that he was able to dress himself and attend to his wants, and was interested in his surroundings. Ataxic aphasia soon took the place of the complete aphasia which had prevailed for six months. This gradually faded away with the improvement in his general mental condition, and he was able to converse rationally, his articulation becoming perfect. He then gave me a history of syphilis contracted two years before. The primary lesions were slight, and he had no recollection regarding the appearance of the secondary phenomena. He was discharged cured, so far as his insanity was concerned, six months after admission. He had gained forty-five pounds in weight, and had all the indications of good health. He is now married, and follows his trade, that of a painter and decorator, in Chicago. One and one-half years have elapsed since he was discharged, and as yet he has had no evidences of a return of the disease.

This case is interesting because of the long duration of functional disorder of the brain, and the subsequent complete recovery, with no evidence whatever of organic change. The pathology of the case can probably be explained by conditions similar in nature to those in the preceding case, namely, an arteritis not sufficient to produce organic changes, but, so far advanced as to affect the nutrition of that part of the brain presiding over the intellectual faculties. The coëxisting aphasia locates the disturbance in the vicinity of the Sylvian artery, for we know that all impairment of speech is due to the involvement of the terminal branches of that artery.

The more common form of cerebral syphilis is, as I have before stated, a tertiary phenomenon, and therefore a disease of tissue.

The following case is typical of gummatous deposit:

CASE III.—Male, aged thirty-five years, married, had syphilis twelve years before admission to the hospital. Three years before, his friends decided to have him committed as insane. He had an apoplectic stroke, followed by hemiplegia, lasting but a short time. Following this a gradual change was noticed in his mental condition; he became forgetful, irritable, and excitable. One and one-half years later he had a second apoplectic attack, with hemiplegia; became partially blind; had partial ptosis of short duration, and strabismus, and declined slowly mentally. Amnesic aphasia then developed, and later partial ataxic aphasia. His physical health on admission was fair. Mentally, he was excitable and delusional, having delusions of grandeur, and believing that he possessed unlimited wealth and power.

One evening, while at supper, about three months after admission, he suddenly became unconscious, fell to the floor, and had a severe convulsion, followed by a variety of symptoms, indicating a general effusion into the lesion. He regained consciousness in about twenty-four hours, but was more or less somnolent for several days, after which time he seemed to be about as usual. He declined slowly in general health, and paretic symptoms became marked and variable. Four months later he again became unconscious, and had several severe convulsions, followed by profound coma, which lasted until his death, nine days later. The paralytic symptoms observed from the inception of the disease until death were briefly as follows: Ptosis, at first transitory, but at last becoming permanent, and loss of accommodation, with bulging of the eyes. This group of symptoms indicates involvement of the third nerve, and considered with the headache which was localized, more or less persistent, and unusually severe at night, suggests syphilis. (Jackson.) Further, the involvement of the sixth nerve, as indicated by transitory internal strabismus, due to paralysis of the external rectus muscle, indicates syphilis. Aphasia, progressive, and ultimately complete, showed complications in the vicinity of the Sylvian artery, which resulted in complete destruction of the artery, as verified by post-mortem examination. Hemiplegia, at first short in duration, afterward permanent, was primarily due to impeded circulation, finally to occlusion of the middle cerebral artery. Hemiplegia, accompanied with loss of consciousness, can always be attributed to intracranial disturbances. The bedsores which developed on the nates, heels, and elbows, showed indication of impairment of the trophic nerve-fibres.

The psychical symptoms were varied, and slow in development, delusions of grandeur being especially marked. Such delusions are characteristic of certain specific cases. The post-mortem examination revealed further evidences of the existence of syphilis. The dura and pia were matted together, which, according to Meyer, is pathognomonic of syphilis. A deposit of granular tissue, similar to that found in syphilitic growths, was found at the base of the brain, in the region which the focal symptoms had indicated. H. C. Wood says it is well known that morbid exudations, not tubercular or syphilitic, are rare in this region, and this fact, taken into consideration with the abrupt and variable paralytic symptoms, strongly point to syphilis as the cause of the patient's brain-disease.

The following case shows the strong relationship between cerebral syphilis and general paralysis:

CASE IV.—Patient was a male, aged forty-four years, married. A gradual change had been noticed in his disposition and mental power for more than a year previously to his admission to the hospital. He became forgetful, irritable, and even homicidal, and attempted to kill his wife. On admission he had the following paretic symptoms: Tabes dorsalis, lack of general muscular coördination, and marked impairment of articulation. The pupils were unequally dilated, the right being the larger, and bodily nutrition was impaired. The mental symptoms were characteristic of general paralysis, viz.: Delusions of grandeur, he believing himself the owner of the world and all its wealth.

He had had the initial lesion of syphilis fifteen years before. His history subsequent to admission was that of general paralysis, and, after admission, slow decline, with occasional intermissions, when he would improve only to lose more ground when the decline began again. On the day before his death he had an epileptic convulsion, and on the day of his death two more, the last one proving fatal.

The relationship between cerebral syphilis and general paralysis is hard to establish, because of the unreliability of statistics (Gowers); but Dr. C. J. Folsom[1] believes that the relationship is proven to be not accidental, for two-thirds of all general paralytics are syphilitics as well. Dr. Folsom does not regard it as a stage of syphilis, nor amenable to syphilitic treatment. Dr. S. Weir Mitchell believes in the relationship, and, to a certain extent, in the curability of general paralysis by syphilitic treatment. In a recent number of the *Journal of Nervous and Mental Disease* is an abstract of a paper by Dr. Cuylits, of France, in which the author mentions three theories concerning the relationship between syphilis and general paralysis, viz.: (1) that general paralysis always has syphilis as a cause; (2) that syphilis never causes general paralysis; and (3) that syphilis exercises some influence upon its production, whether as a determining or as an occasional cause. Another view is, that general paralysis indirectly predisposes to syphilis. The general paralytic during the stage of excitement that precedes the development of the malady gives way to every kind of excess, and is particularly liable to syphilis. This important question is now before alienists and neurologists, and we await developments that will clear up the pathology of both diseases, and establish the true relationship between them. I would say that I am convinced of the very close kinship of these diseases, and regard general paralysis as due to syphilis in at least eighty per cent. of all cases.

The few cases which I have reported represent the heterogeneousness of nervous syphilis, and while it may be admitted that there are no symptoms which are really pathognomonic of cerebral syphilis, and which will enable us at all times to diagnose it, yet it may be maintained that when we consider a case as a whole, observing the symptoms from their inception, how they begin their course, how they are associated, yet dissimilar, and how they end, there is often good reason for a diagnosis of cerebral syphilis. Sometimes, when we are even then in doubt, if we will but apply the therapeutic test of anti-syphilitic treatment, we can clear up all the doubts.

A REPORT OF ONE HUNDRED SINGLE MAJOR AMPUTATIONS PERFORMED AT ST. LUKE'S HOSPITAL, SOUTH BETHLEHEM, PA.

BY LARKIN W. GLAZEBROOK, M.D.,
OF SOUTH BETHLEHEM, PA.

THOSE interested in the rapid advance of surgery will certainly read with interest and perhaps with instruction the following simple statistical collection of amputations performed according to modern methods. The one hundred cases which I wish to report are the sum total of all the single, major amputations performed in St. Luke's Hospital between January 1, 1888, and October 19, 1890.

Before giving the statistics, it may be of interest, especially to young hospital surgeons, and to those who have not had the advantage of hospital experience, to be told in a few words by what means we get results which are certainly flattering. Therefore, I will describe as concisely as possible an ordinary "everyday" case requiring amputation. As will be seen further on, ninety-three of these cases were due to some accident—in almost every case a railroad injury. The case generally has been injured from four to ten hours previously, and has been lying in a crowded railroad station before being taken to the South Bethlehem depot, where a single dressing is hurriedly applied. The injured person is then carried in five minutes by the ambulance to the hospital. On his arrival he is immediately placed on the operating table, and his clothes, as far as practicable, removed.

If he is badly shocked, he is left with the nurses, who surround him with hot cans and, at the same time, stimulate him either by the mouth or hypodermically. Here let me say, that we know of no more effectual stimulant than what is called in the hospital "strong medicine," the formula for it being the following:

℞.—Tincture of digitalis . . . . 5 minims.
Aromatic spirit of ammonia } of each 10 "
Compound spirit of lavender }

This is given as often as the condition of the patient may indicate.

It is very unusual for us to amputate while the patient is in a condition of shock, although two of our deaths occurred during shock. When the patient is in the proper condition, he is anæsthetized by one assistant, while the other pays the strictest attention to the injured part. First, turpentine is freely used to remove the grease, etc., which in so many cases literally covers the wound and adjoining skin. The condemned part is thoroughly douched with a 1-to-1000 solution of bichloride of mercury and wrapped in a wet bichloride towel. After this, a large area is lathered with warm water and green soap, and shaved. Then the parts are scrubbed, first with alcohol, and, finally, 1-to-1000 bichloride solution. While these preparations are going on the nurses are attending to the sterilization of the instruments, dressings, etc. It is hardly necessary to say that hands, sponges, in fact, everything in the slightest way connected with the operation, must be immaculate.

By means of elevation and an Esmarch bandage, the limb is made bloodless. Here let me say, that many of our cases have had great damage done to the tissues, when they arrive, by strings or knotted handkerchiefs very roughly applied. This damage has been much less since the railroad men, and especially those of the Lehigh Valley Railroad, received instructions in applying tourniquets, etc., by Dr. Estes in one or two public meetings.

As to the different methods of operating, we never transfix our flaps. Skin-flaps are invariably used, and in all cases, except in a few amputations of the forearm and lower third of the leg, the antero-posterior flap is the one selected. In the latter situation we have been unusually successful with lateral skin flaps, and by means of them drainage is always assured without a counter-opening. After the bone or bones are sawn through, the next most important thing is to be sure that all bleeding vessels are ligated. Particular stress should be laid on checking hæmorrhage, as it is too often hurriedly passed over. Take a little more time, and either twist or ligate everything, even the smaller muscular branches, which may be seen oozing. Owing to great care in this particular, we rarely have any bleeding when the Esmarch is removed, unless it be slight oozing from the end of the bone.

After the edges of the bone have been trimmed and the nerves cut short, the wound is thoroughly douched with 1-to-1000 bichloride solution. Next, two or three deep silver sutures are passed perpendicularly to the long axis of the bone through the cut muscles. This is particularly useful in thigh amputations; it prevents to a certain extent retraction of the muscles, and in this way gives a more rounded and useful stump. The wires are fastened by means of small wooden pegs. Drainage being provided for by means of one long or two short rubber-tubes, the line of incision is closed with interrupted silk and continuous catgut sutures. The line of incision is now covered with gutta-percha protective, which has been sprinkled with iodoform. The regular Lister dressing is then applied, *i. e.*, iodoform and bichloride gauze, and the whole is covered by one or two carbolized jute pads.

The patient is now carried to the ward, where hot cans are applied, and an order is given for him to have several doses (one-half ounce each) of black coffee as soon as he can swallow.

The primary dressing is allowed to remain for nine or ten days, unless there should be a rise of temperature or oozing, when the wound is immediately re-dressed. The sutures and tubes are removed, as a rule, between the sixth and the tenth day. If there is any gaping of the wound, it can generally be overcome by adhesive strips and tight bandaging.

I will now give in figures the results of all these apparently small, but yet most valuable, suggestions. In the one hundred cases reported there were only seven deaths following amputation, or a percentage of ninety-three recoveries. Two of the seven fatal cases were operated upon during shock. The five other cases died from exhaustion, following loss of blood which had previously taken place. The total number of days spent in the hospital by the ninety-three cases which recovered was 2115; average number of days for each patient 22.6. Seven amputations were for disease, with no deaths.

Amputation of the forearm, lower third, antero-posterior flaps	13

OBSERVATIONS ON THE USE OF KOCH'S LYMPH IN SIXTEEN CHILDREN.

BY EDWARD CHARLES WENDT, M.D.,
ATTENDING PHYSICIAN TO THE NEW YORK INFANT ASYLUM AND TO ST. JOSEPH'S ASYLUM; CURATOR OF THE ST. FRANCIS'S HOSPITAL, ETC. NEW YORK.

AT the present writing I have employed Koch's lymph in seventeen cases. Sixteen of these cases were children of various ages, from nineteen months to sixteen years. These sixteen cases form the basis of this report. Two of them are under observation at the New York Infant Asylum, the others at the St. Joseph's Orphan Asylum. One decided advantage of treatment at the latter institution is due to the circumstance that the children will remain under surveillance for a long time, and that the developments of the lymph-treatment are thus reasonably sure to be seen. In ordinary hospitals, patients generally remain but a short time, and their subsequent history is often entirely a matter of speculation. Treatment by Koch's lymph is of such recent origin, and some of its results are so surprising, that for some time to come every case will be of more or less interest. But after temporary manifestations shall have been studied on a sufficiently large scale, then its more lasting effects, if it has any, will demand our attention. Preliminary notes on eight of these cases were published in THE MEDICAL NEWS of January 3, 1891.

A few words as to the selection of new cases are in place here. I have not selected any patients with readily demonstrable phthisis. The lymph has been employed by others in hundreds of such cases. That they show a febrile reaction after inoculation is now known. Whether they can be cured remains to be seen. But there is a large class of cases that are merely "suspicious." Strumous children, strongly tainted by heredity and predisposed by early environment, but without signs of already existing consumption, form no mean proportion of the inmates of many orphan asylums and similar institutions. Now, if the Koch fluid is really a sure test for tuberculosis of all kinds, then children that react are already tuberculous, while those without reaction should be considered free from the actual disease. There ought to be few, if any, exceptions to the proper working of such a rule if the doctrine of Koch is to stand. Cases with merely premonitory manifestations, even if thus shown to be already affected, should likewise be more amenable to treatment than those of a more positive and advanced kind.

In a general way, I have found that during the period of febrile reaction the children are certainly sick. But even with a temperature of nearly 106° F., and a correspondingly rapid pulse-rate and respiration, they seem more alert, less profoundly affected, than in any morbid state known to me which is accompanied by similar constitutional disturbances. It is true the pulse is at times quite feeble, but I have not yet seen anything approaching dangerous collapse. Severe headache appears to be the most common symptom, and next to that the development of cough. An exanthem resembling scarlatina or measles, and conjunctival injection have been noticed several times, but vomiting has been infrequent, and diarrhœa has not been complained of.

Children appear to bear the lymph well enough, and tolerance to increasing doses is seen in them just as in adults. They also recover from the prostration incident to reaction in a surprisingly short time.

For the present I have adopted the rule to give at the first inoculation 0.00025 gramme of the fluid, even in children more than ten years old. The reinoculations are increased to 0.0005 gramme, or even 0.001 gramme, according to the intensity of reaction. The only other general observation which I wish now to record, is that the febrile reaction may be postponed for twelve or even eighteen hours, and that it may last for two entire days.

The following brief notes of the cases will serve to illustrate these remarks:

CASE I. (*Of previous report.*) *Strong hereditary predisposition to phthisis.*

December 30. Sixth inoculation of 0.003 gramme. Temperature rose to 101.8° F.

January 2. Seventh inoculation of 0.004 gramme at noon. In nine hours the temperature was up to 102.4° F., and at 11 P.M. it was 103.4° F. Intense headache.

3d. Slight cough has developed. Temperature rose to 101° F. in afternoon, but subsided to 99° F. by 9 P.M.

5th. Eighth injection of 0.0045 gramme. To-day for first time fine crepitant râles are heard over left, upper posterior part of chest. Painful redness at site of last injection.

6th. Redness fading, very little local pain left.

8th. Her only sister having just died of phthisis, no injection was made, although temperature was normal.

9th. Ninth injection of 0.005 gramme. Reaction to 100.4° F.

10th. A few râles (finely crackling) heard on deep respiration in front on left side at apex.

11th. Temperature 98.4° F. in morning. Tenth inoculation of 0.006 gramme. Temperature rose to 100.4 F.

12th. To-day temperature remained almost stationary at 100.5° F. Her appetite is at present better than before treatment was begun.

CASE II. (*Of previous report.*) *Ozæna scrofulosa, and lymphadenitis of neck.*

December 30. Sixth injection of 0.003 gramme. Temperature rose to 101° F.

January 2, 4, and 6. Injections up to 0.005 gramme. The cough, which was so conspicuous a feature after the first few injections, is much less now. On the right side of the neck the glands (excepting one the size of a small walnut) are scarcely appreciable to the touch. On the left side they are smaller and harder than before, but still quite large. Reaction to 103° F.

8th. 0.0055 gramme injected. Very slight reaction. Temperature 99.8° F. Ulcers healing under crust.

9th. Injection of 0.006 gramme. Reaction to 102° F. Pain in back. Nose looks swollen; puffy redness of cheeks.

11th. Injection of 0.007 gramme. Temperature rose to 103° from 98.4° F. in the morning. Felt "sick all over" several hours after injection.

12th. Erysipeloid swelling about nose—*i. e.*, site of ulceration. All glands rather smaller; they show no local tenderness or other signs of inflammatory reaction.

CASE III. (*Of previous report.*) *Hip-joint disease.*—Re-inoculations December 30th, January 2d, 4th, 7th, and 10th, up to 0.004 gramme. On January 2d, temperature rose to 104.4° F. in ten hours after injection. The joint was more sensitive to manipulation after first few injections, is less so now. There is greater mobility of joint. The reactions are much less severe now, temperature only rises to about 100.5° F.

CASE IV. (*Of previous report.*) *Hip-joint disease.*—Only two inoculation made, 0.002 gramme each on December 30th and January 3d, as the temperature has not returned to the normal point, fluctuating between 99° F. and 100.4° F. Several large glands, only slightly tender, are found deep in the iliac fossa on the affected side. There is a slight bedsore. Child in extension apparatus.

CASE V. (*Of previous report.*) *Tubercular glands in neck and submaxillary region. Scrofulous affection of eyelids and nose.*

December 30. Injection of 0.001 gramme. Temperature rose to 102.4° F.

January 2. Injection of 0.0015 gramme. Temperature 98.4° F. at time. In ten hours it rose to 102.6° F. Desquamation of skin in shreds, exactly as in scarlet fever.

4th. Injection of 0.002 gramme. Slight reaction to 100° F.

5th. Temperature rose to 101° F. this P. M.—*i. e.*, late or postponed reaction.

6th. Injection of 0.002 gramme. Highest temperature 100.8° F.

7th. Temperature 100.2° F. in the morning, 99° F. P. M. The râles at apices less distinct to-day, but breathing harsh, expiration prolonged. Little cough.

8th. Injection of 0.003 gramme.

10th. To-day there are moist crepitant râles, mostly small over the entire left side, both in front and behind. This is a new symptom.

11th. Temperature 97.6° at 9 A. M. Injection of 0.0035 gramme at 11.30 A. M. At 7 P. M. temperature 103.6° F.; at 9 P. M. 104.2° F. Very nervous and restless at night. On leaving her bed was noticed to walk with decidedly staggering gait.

12th. Pulse small, 160 beats per minute. Conjunctivæ injected. Râles the same on left side, none on the right side. Temperature fell to 101.6° F., but rose again this P. M. to 103.0° F. This girl was very much emaciated before treatment, but is now gaining flesh. Appetite fair.

CASE VI. (*Of previous report.*) *Incipient phthisis.*

January 1. Fewer râles. Expiration harsh and prolonged at apices. More dulness on right side.

2d. Injection of 0.003 gramme.

3d. Eruption like measles all over body, except legs. Some urticaria-like wheals. Temperature rose from normal to 104.8° F. in eight hours.

4th. Fewer râles. Rash fading.

5th. Still some rash. Injection of 0.0035 gramme. Followed by violent subjective symptoms. Intense headache, screaming with pain. Constant dry cough. Vomiting. In three hours the temperature went up to 100.8° F. At 6 P.M. it was 101.4° F.; at 8 P.M., 104.4° F.; at 9 P.M., 105.8° F.; at 10.30 P.M., 105.2° F.; at midnight, 104.2° F.

6th. Temperature gradually subsiding.

7th. Temperature still around 100° F.

8th. Temperature normal this A.M. Injection of 0.004 gramme. Temperature again quickly rose to 103° F. in three hours. At 5 P.M., 104° F.; at 6 P.M., 105.4° F.; at 7 P.M., 105.6° F.; at 9 P.M., 105.8°; at 11 P.M., 105.2° F.; at midnight, 105° F.

9th. Temperature 100.6° F., to 101° F. Pulse weak and rapid. Backache, headache. No appetite.

10th. Fine crackling râles all over right side, especially behind. Also more râles on left side—*i. e.*, extension of pulmonary process. Cough dry. Very slight expectoration. Highest temperature 100° F.

11th. Temperature normal this A.M. Injection of 0.0045 gramme. Temperature rose to 104.6° F., but no violent symptoms appeared.

12th. Temperature down to 98.4° F. No afternoon rise. Fewer râles. Less cough.

In Case VII. the inoculations were discontinued, as there was no further reaction after sufficiently large doses had been reached. According to Koch's doctrine, the condition of this little girl should, therefore, be regarded as at present "non-tubercular." This would accord with the fact previously noted, of her recovery from an attack of meningitis closely simulating the tubercular variety. This child has certainly not been made worse by the inoculations. Her general condition remains entirely unchanged. In the present stage of experience negative evidence may be just as instructive as that of a positive nature.

CASE VIII.[1] *Phthisical thorax; enlarged cervical glands; "suspicious" breathing at apices.*—Girl,

[1] Cases VIII. to XIV., inclusive, are the new cases at the St. Joseph's Asylum. Case VIII. of previous report is Case XV. of this one. Case IX. of previous report, being an adult case, is omitted, and Case XVI. is the new case at the New York Infant Asylum.

aged twelve years. Family history good. Is thin and delicate; very narrow and flat chest. The breathing at apices is harsh, but there are no râles of any kind. No cough. Chains of enlarged glands of neck, running down to supraclavicular region.

January 5. Injection of 0.00025 gramme. In six hours temperature rose to 101° F.

6th. A.M., temperature, 98.8° F.; 4 P.M., 102° F.

7th Injection of 0.0005 gramme. Temperature rose to 101.4° F. Scarlatinoid appeared over entire body.

8th. Rash present.

9th. Rash fading. Slight cough.

10th. Still a remnant of rash. Injection of 0.001 gramme. Temperature 99.4° F. only.

11th. Temperature to-day higher than yesterday, up to 101° F.—*i. e.*, postponed reaction. Rash has reappeared, but only on trunk.

12th. Glands in supraclavicular region smaller. No râles, but slight cough continues.

CASE IX. *Scrofulous ulceration; fœtid otorrhœa; cervical lymphadenitis.* —Girl, aged eight years. Lungs negative, no cough. Corneal opacities and various scars indicate former morbid processes. At present only slight ulceration of lip and nose. Chains of enlarged glands on either side of neck.

January 5. Injection of 0.00025 gramme. Temperature rose from 98.4° to 99.4° F.

6th. Injection of 0.0005 gramme. Temperature rose to 100° F.

8th. Injection of 0.00055 gramme.

9th. Injection of 0.001 gramme.

10th. Injection of 0.0015 gramme.

11th. Injection of 0.002 gramme. Temperature never rose above 102.8° F.

12th. Temperature 97.4° in morning. Corneal opacities are unmistakably less dense, otherwise no change. Scarcely any subjective symptoms.

CASE X. *Winter cough; suspicious breathing at right apex.*—Girl, aged eleven years. Has coughed every winter for a number of years. Right supraclavicular space retracted, expiration harsh and prolonged over this region. No râles. Small eater. Slight glandular chains at neck.

January 5. Injection of 0.00025 gramme. Cough increased; pain in chest. In six hours temperature rose to 101° F.

6th. Temperature at 11 A.M., 100° F.; at 4 P.M., 100.6° F.

7th. Injection of 0.0005 gramme. Temperature not above 100° F.

8th. Temperature 100.6° F.—*i. e.*, slight late reaction.

9th. Injection of 0.001 gramme. Temperature rose to 100.8° F. only.

10th. Has vomited a number of times. On left side below scapular spine râles have developed.

11th. To-day there are râles on right side also, near sternum.

12th. Injection of 0.002 gramme. Temperature rose from 98° to 99.4° F.

CASE XI. *Suspicious apices; hereditary predisposition to phthisis.*—Girl, aged fifteen years. Parents both died of consumption. One sister "delicate." Has coughed for eight years. Small eater. Paralytic thorax. Slight retraction at apices. Supraclavicular spaces sunken in during inspiration. Very few râles, apparently bronchitic. Pain over chest.

January 5. Injection of 0.00025 gramme. Temperature did not rise above 99.4° F.

6th. Temperature remained almost stationary at 100° F. all day.

7th. Injection of 0.0005 gramme.

8th. Injection of 0.001 gramme.

9th. Injection of 0.002 gramme.

11th. Injection of 0.0025 gramme.

12th. Injection of 0 003 gramme. A few râles are now heard, but there has been no marked febrile reaction, the highest temperature having been only 100.8° F.

CASE XII. *Aggravated pigeon-breast; ulcerative processes of lips and eyes; large cervical glands.*—Boy, aged ten years. Thorax deformed into a pronounced pigeon-breast. Thin, pale, delicate-looking. Lungs negative. No cough. Glands in left side of neck quite large.

January 5. Injection of 0.00025 gramme. Temperature rose to 100° F. in four hours. Nausea, pain in stomach, great malaise.

7th. Injection of 0.0005 gramme.

8th. Injection of 0.001 gramme.

9th. Injection of 0.002 gramme.

10th. Injection of 0.003 gramme. No noteworthy febrile reaction, highest temperature 100.4° F.; cough has come on, but no râles are heard.

CASE XIII. *Scrofulous ulcerations; lymphadenitis.* —Boy aged six years. Ulcerative processes of neck, chin, lips, and nose. All glands enlarged. Largest about the size of a cherry. Lungs negative.

January 9. Injection of 0.00025 gramme.

10th. Injection of 0.005 gramme.

11th. Injection of 0.001 gramme. Some of the ulcers covered with crusts. Some eczematous patches are now dry. Diffuse redness about them.

12th. Injection of 0.002 gramme. Redness noticed yesterday subsiding, Only slight febrile reaction to 100.6° F. so far. No cough.

CASE XIV. *Suspicious apices; phthisical thorax.* —Boy, aged thirteen years, brother of Case IX. Very flat chest. Retraction of supra- and infraclavicular spaces on both sides. Harsh apex-breathing. No cough. No râles. Superficial ulcerations about nose and eyes. Submaxillary lymph glands in left side almond size.

January 11. Injection of 0.00025 gramme. No reaction.

12th. Injection of 0.00055 gramme. Reaction to 101.8° F.

CASE XV. (*This is Case VIII. of previous report.*) *Tubercular lymphadenitis of neck.*

December 29. Temperature rose to 103° F. after injection of 0.0005 gramme.

31st. Injection of 0.001 gramme, with rise to 102.6° F. Cicatrix quite red. Child bright and playful; sleeps well.

January 2. Injection of 0.00175 gramme at 7 P.M Reacted to 102.6° F. by 6 A.M.

4th. Scar looks better, less bulging, less red. Injection of 0.0002 gramme, not followed by reaction.

5th. Temperature normal. Cicatrix no longer indurated. Redness almost gone.

8th. Injection of 0.002 gramme. No reaction.

10th. Scar has diminished fully one-third in thickness. Other glands smaller. Child seems well.

12th. Injection of 0.002 gramme.

CASE XVI. "*White swelling*" *of the knee.*—Child, aged two years, has had plaster bandage immobilizing knee-joint for weeks without benefit.

January 12. Injection of 0.00025 gramme. Moderate reaction.

CLINICAL MEMORANDUM.

SURGICAL.

Position and Fomentations in the Treatment of Strangulated Hernia.—On the morning of November 21, 1890, I was called to see a German woman, married, aged forty-two years, suffering from strangulated omental femoral hernia. The tumor was the size of an almond, very tender, and unyielding to the touch.

The hernia made its appearance at 4 P. M. on the previous day. While the patient was in a stooping position, one foot suddenly slipped from a board, when she felt a severe and lancinating pain in the region of the femoral ring.

After making an unsuccessful attempt at reduction by taxis under chloroform, I decided to try conservative treatment rather than hazard an operation with the very unfavorable surroundings.

Consequently, I had the foot of her bed elevated about fourteen inches, and ordered tobacco fomentations, as hot as could be comfortably borne, to be constantly applied to the tumor. I gave the patient ¼ grain morphine and $\frac{1}{120}$ grain atropine, hypodermically, and left her. On returning in six hours I found the tumor smaller, more yielding, and less tender to the touch.

Forty-eight hours after first seeing the patient the tumor had entirely disappeared, without any untoward symptoms except some nausea caused by the tobacco fomentations and morphine.

I have had excellent results from the same plan of treatment in severe renal colic that would not yield to morphine. In the use of tobacco for the relief of such cases as herein noted, it must be applied in quantities sufficient to secure its physiological effects. My custom is to use one-half pound of good smoking tobacco for each fomentation.

W. D. JONES, M.D.

RISINGS, NEBRASKA.

MEDICAL PROGRESS.

Ointment for Chilblains.—The *Weekly Medical Review* quotes the following formula for an ointment used by DR. MORROW in the treatment of chilblains:

R.—Carbolic acid . . .	1 drachm.
Tincture of iodine . .	2 drachms.
Tannic acid . . .	1 drachm.
Simple cerate . . .	3 ounces.—M.

Apply to the affected parts two or three times daily.

Operative Treatment of Tubercular Peritonitis.—The Berlin correspondent of the *Lancet* (December 20, 1890) writes that at a recent meeting of the Public Health Society, FRÄNKEL exhibited a young man who had been cured of tubercular peritonitis by abdominal section. The patient had come under Dr. Fränkel's care some months previously, and was then extremely reduced, and had ascites, manifestly due to tuberculosis. A median abdominal section was made, and the ascitic fluid evacuated. As a result, the patient, when exhibited, looked well and strong, the wound had united, and there was no abdominal tenderness or other symptom of disease.

A Successful Pericardiotomy.—According to the *St. Louis Medical and Surgical Journal*, January, 1891, STOLL, of Warsaw, has reported a successful operation for purulent pericarditis. The patient was an exhausted and emaciated soldier, twenty-one years old. After the sternum was trephined the pericardium was freely opened at the level of the second intercostal space. Two months after the operation, examination showed that the pericardial sac was completely obliterated. This is said to be the fourth successful case on record.

Auscultatory Percussion in the Diagnosis of Abdomina Tumors.—ZUELZER (*Centralblatt f. d. Physiologie und Pathologie der Harn und Sexual Organe*) recommends combined auscultation and percussion in the examination of the kidneys and of abdominal tumors covered by a thick layer of muscle. Differences of sound incapable of recognition by ordinary percussion can thus be determined. A metallic vibrating sound is given by organs containing air such as the lungs and intestines. If we percuss over a solid organ, such as the heart and liver, or over tumors, or if we percuss below the solid mass and auscultate at the upper margin, marked interference with the sound-conduction is appreciated. In this manner we can map out the borders of organs or tumors with accuracy. To detect the boundaries of the bladder when filled with urine, the stethoscope should be placed over the intestines above the bladder during percussion.

In examination of the kidneys it is necessary to determine the position of the external and inferior borders. For this purpose the intestines should be as empty as possible. The stethoscope is placed upon the anterior abdominal wall, and percussion practised over the corresponding renal area, while the patient bends slightly forward. Percussion should be commenced at the level of the fifth or sixth lumbar vertebra over the spinous process, and is then continued outward. Over the bone the resonance is clear. Where the kidney is covered by the muscles of the back the percussion-dulness is most intense, the sound becoming clear when the percussion is carried beyond the borders of the organ.—*Journal of Cutaneous and Genito-urinary Diseases*, January, 1891.

Irrigation of the Colon in Dysentery.—DR. PETR S. KORYTIN (*Vratch*, No. 42, 1891) details his experience in the treatment of dysentery by the use of large enemata. Fifteen consecutive cases were treated by this method, of which but one died, the remainder making good recoveries. Six pints of water, at a temperature of 102° F., were used for each enema. The injected fluid was

usually retained for from five to ten minutes. In three catarrhal cases simple tap-water was used. In the remaining cases from ten grains to one drachm of crystalline carbolic acid were added to each enema, but the effects of the latter did not differ in any way from those of the pure-water enemata. The treatment caused a rapid decrease of abdominal distention and pain, tenesmus, and frequency of stools. Appetite and sleep soon returned, and the stools quickly became more solid, and free from offensive odor, as well as blood, mucus, and shreds, while the temperature fell to normal. In catarrhal cases improvement was more rapid than in diphtheritic cases. The good results are attributed by Dr. Korytin simply to the thorough cleansing of the large intestine.—*St. Louis Medical and Surgical Journal*, January, 1891.

The Treatment of Tinea Tonsurans.—In the treatment of this troublesome affection CARRERE, in an inaugural thesis, details the methods which have been practised at the Hôpital St. Louis by various physicians in attendance.

That of BAZIN consists in the removal of the hair of the affected part, in the application of lotions of corrosive sublimate of the strength of 1 to 250 and the employment of a parasiticide ointment composed of the acetate of copper, the iodide of sulphur or of turpeth mineral.

The treatment of VIDAL consists in rubbing of the affected part with the oil of turpentine and painting with tincture of iodine. Second, in the application to the scalp of iodized vaseline in the strength of 4 to 100, covering the head with a piece of rubber tissue or other impermeable substance.

BESNIER removes the hair for from 6 to 8 millimetres beyond the spot which is affected, and aids in the removal of the parasite by the use of a curette. After this he orders daily washings with soap, tar, salicylic acid or sulphur. Finally he applies a piece of mercury plaster over the part which is diseased.

HALLOPEAU orders the head to be washed with green soap every morning, and afterward that the following prescription should be rubbed into the affected area.

℞.—Spirit of camphor . . 6 ounces.
Spirit of turpentine . . 6 drachms.
Ammonia water . . . 1½ "

Half an hour after this iodized vaseline in the strength of 1 to 100 should be applied, and, as with the treatment of Vidal, a caoutchouc covering should be placed on the head. Another application of the iodized ointment should be made at night.

UNNA, of Hamburg, employs the following ointment under these circumstances:

℞.—Salicylic acid . . . . 30 grains.
Chrysarobin . . . . 75 "
Ichthyol . . . . . 75 "
Simple cerate . . . . 5 ounces.

This is to be applied to the head and a rubber or other impermeable cap placed upon the patient. After using this ointment for four days applications of 5-per-cent. ichthyol ointment should be employed, and at the end of the week this line of treatment should be followed for a second time.

QUINQUAND directs that the head shall be washed with soap and hot water, and the following lotion be applied with friction:

℞.—Biniodide of mercury . . 2½ grains.
Bichloride of mercury . . 15 "

These are to be thoroughly mixed in a mortar and dissolved in ½ ounce alcohol (90 per cent.), and distilled water 6 ounces. The part which is affected should be energetically scraped with a curette after the employment of this lotion, and a plaster made of biniodide of mercury, 2½ grains; bichloride of mercury, 15 grains, and simple cerate, 6 ounces, should be applied. After this application is discontinued the head is once more washed with soap, and frictions are again made with the lotion which has been named. This course of treatment is to be repeated until the cure is complete.

In some cases the following ointment has been found to act equally well with the mercurial ointment just named: chrysophanic acid, salicylic acid and boric acid, of each 30 grains.

Treatment of Acute Tonsillitis.—SURGEON HEHIR (*Indian Medical Gazette*, November, 1890), in cases of acute tonsillitis recommends the administration of pilocarpine to relieve the distress caused by the accumulation of tenacious pharyngeal mucous. One-eighth of a grain in a teaspoonful of water every two hours, or ⅛ grain hypodermically every four hours, until slight salivation is produced, is sufficient. Locally he uses repeated poultices and constant steaming by means of boiling water near the patient's head. Internally, tartar emetic in doses of $\frac{1}{16}$ grain to adults every two hours has given him more uniformly good results than any other drug, not excepting sodium salicylate. If any depression follows the use of the tartar emetic, which is unusual, ammonium carbonate or strophanthus may be given. Of stimulants he thinks port wine the best and believes that it has some local beneficial action upon the inflamed tonsils. Guaiac mixture is sometimes very useful in relieving the shooting pain often complained of during the act of swallowing. It is usually good practice to begin treatment by the administration of a mercurial followed by a saline purge. Dr. Hehir has repeatedly seen marked relief follow a simple puncture or small incision of the tonsil, and this should be done whenever the gland is greatly swollen. It is much preferable to the use of leeches in the submaxillary region. He believes that strong astringent gargles are of very little use during the acute stage, but that tepid antiseptic gargles may be beneficial.

Ointment for the Chloasma of Pregnancy.—

℞.—White precipitate . . . 1½ grains.
Purified oxide of zinc . . 4 "
Cocoa butter } of each . . 1½ ounces.
Castor oil }
Essence of rose, a sufficient quantity.

Apply this with gentle friction twice a day to the pigmented spots. In the morning it may be well to wash the parts with hot water and to apply an ointment composed of

℞.—Kaolin } of each 2½ drachms.
Subcarbonate of bismuth }
Vaseline . . . . . 1½ ounces.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

VIRCHOW AND KOCH.

THERE is probably no one living whose opinions are listened to with the same respect as are those of Virchow, who has been so correctly called the "father of modern pathology." The statements of this eminent man are also particularly interesting when they concern the new method of treating tuberculosis, and become still more important when they seem in any way opposed to the almost ecstatic reports of the physicians who have used the mystic liquid in Germany and elsewhere.

The statements of Virchow, which are published in the *Extra* attached to this number of THE MEDICAL NEWS, show that a possibility exists of a sad curtailment of our hopes for the relief of the "white plague," and emphasize the fact that, do what we will, the mortality must go on unimpeded to a very great extent.

The fact that the bacilli greatly increase in numbers under the use of the anti-tubercular fluid has not only been noticed by Virchow, but by others, not the least of whom is Osler, of Baltimore. It would appear that about the Koch method there is being drawn, as with all new remedies when on trial, a constricting band of limitation which may perhaps only serve to outline its uses, or become still more tense, and destroy its life.

THE MEDICAL NEWS has done much toward keeping the profession in America in touch with this entire subject by reason of its several cablegrams, the abstracts from foreign journals, and the original studies made in the great cities of America which it has published and it can assure them of a continued activity and foresight which cannot fail to accrue to their benefit.

CURRENT LITERATURE.

WITH this issue of THE MEDICAL NEWS a new departure for the benefit of our readers is instituted. In addition to the Progress columns, which contain only those short articles which are intended for hurried reading, and general information, we will frequently publish more lengthy condensations of current literature taken from foreign journals and so translated as to contain all the important portions of a paper without the laborious verbosity of the French and German writers. Many such attempts have been made, but in instances not a few the material so published has been so wretchedly abstracted, and so lacking in evidences of judgment as to the essential portions of a paper as to be useless. The existence of an editorial page is often an excuse for foisting upon a subscriber much useless material and for this reason the pages usually so employed in the past in THE NEWS will be taken up with notes on current literature, unless editorial matter is of sufficient interest or value to displace them. By this new move THE MEDICAL NEWS will always be found full of value to everyone and will embrace not only topics of fleeting interest but become valuable as a copious work of reference.

Large Bequests to Charity.—The will of Mrs. Elizabeth Fogg, of New York, gives about half a million of dollars to the hospitals and asylums of that city, out of an estate estimated to be worth $2,000,000.

By the will of the late D. B. Fayerweather, five hospitals of the same city fall heir to about $100,000.

A Chinese Hospital in Brooklyn.—The articles of incorporation have been filed at Albany for a Chinese Hospital Association to be located at Brooklyn. Clergymen and physicians of that city chiefly constitute the board of directors. It will be exclusively for the use of Chinamen, and it is not expected to receive contagious cases.

The Hospital at Atlanta, Georgia.—On December 28th, the corner-stone of the Henry W. Grady Hospital was laid at Atlanta, Georgia, with elaborate ceremonies. The day was the anniversary of the death of Mr. Grady, and was purposely selected as a proper time for these exercises.

CHLOROFORM IN TRACHEOTOMY.

IN a paper advocating the more extensive employment of chloroform in tracheotomy in children, based upon a series of eighty-seven observations, P. GEFFRIER makes the statement that whilst in England and America the administration of chloroform to children operated upon for croup has rapidly grown in favor, and is recommended in the standard text-books, only in exceptional cases is it so employed in France. He regards this as still more remarkable from the fact, that as long ago as 1883 Dr. Gouguenheim, in a paper read before the Surgical Society, stated that in tracheotomy in children, as well as in adults, chloroform is of service; that it does not complicate the operation or render the prognosis more serious; but, on the contrary, that under its use respiration frequently becomes more free and regular, and the appearance of the patient such as to give rise to the hope that the operation will not be necessary. Further, Dr. Gouguenheim thought that chloroform could be used in the paroxysms of suffocation in croup in order to gain time, and in this way render the necessity for tracheotomy less frequent. On the authority of these statements of Gouguenheim, Dr. Geffrier has employed chloroform anæsthesia in all of his cases of tracheotomy since 1887, observing the precaution to administer the chloroform himself.

He places about three grammes of the anæsthetic upon a pad, which is rolled in a towel and held over the nose and mouth of the child, the head of which is less extended than at the time of the operation, as it has been found that prolonged extension gives rise to marked disturbance of respiration. In a very few cases this amount of chloroform was sufficient, but usually two grammes more were required, and in some cases even four grammes, but rarely was more than this amount administered. A remarkable fact which he has noted is, that while in order to produce anæsthesia in ordinary operative cases from four to five minutes are required, in croup, as a rule, but one or two minutes suffice to produce complete anæsthesia.

In the larger number of Geffrier's cases (53 out of the 87) the chloroform was very well tolerated, the only unusual phenomenon observed being the occurrence of short respiratory pauses or periods of apnœa in about one-half of the cases at the commencement of the chloroformization. This condition, however, soon passed away, to be followed by regular and free respiration. Almost invariably consciousness returned at the close of the operation, owing to the small amount of the anæsthetic inhaled. Whenever there was delay in this reaction, tickling the larynx by a small feather passed through the canula instantly produced a reflex laryngeal cough, which resulted in the restoration of the respiratory function. In but 17 of the observations was the chloroform badly tolerated. In these cases there was more or less pronounced cyanosis with short, stertorous respiration, or even momentary arrest of respiration; and in 15 of the cases the operation was performed before complete anæsthesia was obtained. The following conclusions are reached by the author:

1. Chloroform is of undoubted service in tracheotomy in children.

2. It is not more dangerous in tracheotomy than in any other operation, provided that certain contra-indications are borne in mind.

3. The precautions to be observed are as follows:

(*a*) The operator should have prepared in advance, under his own observation, everything which may be needed during the operation.

(*b*) He himself should administer the chloroform, or have it administered by an experienced assistant, following with care the effects produced, and watching the respiration; if there be occasion, he should excite inspiratory movements by artificial respiration or by irritation of the skin (pinching, tickling).

(*c*) The inhalation of chloroform should be immediately stopped, and the operation rapidly performed if the condition of the respiration becomes disturbed. (Rapidly-increasing cyanosis: prolonged apnœa.)

4. As contra-indications to the employment of chloroform anæsthesia may be regarded:

(*a*) The appearance of progressive and complete asphyxia, and profound prostration due to the diphtheritic poison.

(*b*) An appearance of relative asphyxia decreasing in this order:

Marked cyanosis, without disturbance of expiration. Slight cyanosis, with disturbance of expiration.

As contra-indicating chloroform-anæsthesia should not be considered: Slight cyanosis without disturbance of respiration; the early age of the children (if tracheotomy is not contra-indicated by the age, the chloroform is not more so).

5. The chloroform appears to be rather better borne in cases in which respiration is established after one or more paroxysms of suffocation, than in cases in which it is established progressively without paroxysms.—*Revue de Chirurgie*, December 10, 1890.

TONSILLOTOMY AND HÆMORRHAGE.

DR. E. J. MOURE recommends for hypertrophy of the tonsils in children the removal of the organs by the tonsillotome when they are voluminous, jutting out between the faucial pillars, and impeding by their presence the entrance of air into the respiratory passages, and consequently presenting a serious obstacle to the development of the entire organism. In performing this operation, however, it is well to bear in mind the possibility of the occurrence of hæmorrhage, especially in children of the hæmorrhagic diathesis. If this complication occur, not only should gargles and applications be employed—preferably the latter (lemon juice, tannin, solution

of the perchloride of iron, alum, etc.)—but above all, the patients *should be prevented from sleeping during the hours immediately following the operation.* By observing this precaution, the swallowing of blood and the subsequent alarming vomiting of altered blood, accompanied with severe irritation of the gastric mucous membrane, will be avoided.

In the case of adults, Dr. Moure advocates the use of the thermo- or galvano-cautery, giving the preference to the former when it is possible to use it advantageously. He says: "With many of my *confrères* I have often practised tonsillotomy in the child and ignipuncture in both the adult and the child, and always the most perfect success has crowned my efforts. Very often I have reduced tonsils relatively voluminous in one or two sittings by using the thermo-cautery, and I avow that I have never seen patients who believed themselves cured, come to me demanding new treatment. Much more, I think that with the hot iron as much of the tonsil may be destroyed as is desirable, even behind the pillars, if that be necessary, which is not possible with the cutting instrument.

After performing the operation, he prescribes the following emollient and antiseptic gargle:

℞.—Bromide of sodium, Borate of sodium } of each 6 grammes.
Carbolic acid . . . 1 gramme.
Pure glycerin . . . 50 grammes.
Decoction of barley and marshmallow root . . 450 " —M.

This is to be taken during the day. The burned surface rapidly heals, usually without any complications. Occasionally on the separation of the eschar secondary hæmorrhage may occur, which can be controlled by astringent gargles and astringent applications.—*Revue de Laryngologie et d'Otologie et de Rhinologie*, December 15, 1890.

SPECIAL ARTICLES.

REPORT ON THE KOCH TREATMENT OF TUBERCULOSIS AT BERLIN.[1]

BY A. C. ABBOTT, M.D.,
ASSISTANT IN BACTERIOLOGY AND HYGIENE IN THE JOHNS HOPKINS HOSPITAL.

SOON after the publication of the article by Koch upon the effects on tuberculosis of the fluid discovered by him, came reports of the results of the treatment from many of the larger hospitals in Europe. The evidence was of such a nature as to render it important that steps be taken to give to our patients an opportunity to avail themselves of any benefit that might follow the employment of the agent in tuberculous troubles.

With this object in view the Board of Trustees of the Johns Hopkins Hospital decided to send me as their representative to Berlin; my instructions being to make every effort to study not only the clinical features of the method of treatment, but, if possible, to acquaint myself with the nature of the agent employed.

On the morning following my arrival in Berlin, there appeared in the daily papers the address of Minister v. Gossler, made in the Reichstag, on the preceding day. In this address it was stated that the composition of the agent discovered by Koch would be reserved as a government monopoly; not, however, for commercial purposes, but with the view to limiting its employment until its value was thoroughly established.

In a conversation which I had with Professor Koch himself, a short time subsequently, he said that his views were in accord with those of Minister v. Gossler, and he added that the reason for the secrecy was simply to confine the use of the material to the practice of competent observers until its value could be established. When this was accomplished, he hoped to publish a full account of his experiments, and of the technique employed in preparing the virus.

My time was given to the study of the clinical features of the treatment, and through the courtesy of Professors Leyden and Ewald, and Doctors Köhler, Westphal, and Klemper, I had all the advantages that one could wish.

From the cases that I saw in the Charité and Augusta hospitals I feel justified in concluding that the outlook for "surgical tuberculosis" is very favorable. In the lupus-cases particularly, one may say that a cure has been effected in some.

In cases of joint-tuberculosis the injections of the virus have not rarely been repeated until the systemic reaction practically ceased to appear, and still the local expression may have improved but slightly, or not at all. In one such case the joint-cavity was subsequently opened, and in it was found a mass of necrotic tissue containing tubercle bacilli. This tissue was free in the cavity, and had evidently been thrown off from a point on the wall of the joint which still presented the characteristics of tuberculous tissue.

In another case there was every reason to believe that the condition was identical with that of the joint to which I have just referred. At the operation, however, there was an absence of anything in the joint that would lead one to suspect the presence of necrotic tissue. But at one point on the cartilage was an old scar, evidently of tubercular origin, and it is not improbable that the irritation of and effusion into the joint may have resulted from the local reaction in this scar.

In joint-troubles of this character the best results may be expected from the action of the virus, combined with the treatment of the joint by the ordinary surgical measures.

[1] Abstract of remarks made to the Johns Hopkins Hospital Medical Society, January 5, 1891.

The employment of the agent in cases of laryngeal tuberculosis should be conducted with the greatest care, and the treatment should begin with even a smaller quantity of the agent than that ordinarily employed as the minimum dose for other diseases. The extreme congestion brought about in the tissues of the larynx as a result of the treatment is extremely dangerous, if not of a fatal nature.

As is well known, Koch has said positively that phthisical patients in whom the disease has slightly advanced can be cured by the systematic employment of the virus. In his experience such patients were, in a number of instances, pronounced cured after from four to six weeks. He claims further that patients in whose lungs cavities of limited extent exist may be very much improved, and indeed almost cured by this method.

I have not yet seen any of the cases which were reported as cured, though I have seen a number in which the tubercle bacilli were said to have disappeared from the sputum of the patients for longer or shorter periods of time. From my personal experience in the wards in which the pulmonary cases were being treated, I feel constrained to say that it is only with the greatest conservatism that one should express an opinion as to the result of the treatment. There is no doubt that many of these patients gave evidence of improvement, but for one to say positively that they were cured would, I believe, be, at present, a little premature.

The characteristic reaction of the tuberculous patients after injection of the agent begins to appear in from four to five hours after administration. As a rule, it is ushered in by a chill, which is soon followed by a rise of temperature, often to 104° or 105° F.; pains in the limbs; irritative cough; extreme lassitude; and not uncommonly vomiting. Less frequently a temporary icterus of a hæmatogenous nature has been observed, and not uncommonly there appears upon the breast and arms an exanthematous eruption closely resembling that of measles. The attack lasts usually from twelve to fifteen hours. Exceptionally a secondary, though less marked, rise of temperature is seen on the following day.

After the reaction has passed away, there is a conspicuous absence of anything indicating the acute attack through which the patient had passed but a few hours before.

The local reaction can, of course, be best seen in those cases in which the lesion is most superficial, and for this purpose lupus offers the most favorable field. In this group the selective affinity of the agent for tuberculous processes is astonishing. In a few hours after the injection, as the temperature rises, the lupus becomes reddened and swollen. This continues, until through the lupus-tissue there are spots of a brownish-red color. These spots, when sharply circumscribed and isolated, are not uncommonly surrounded by a pale zone, which is in turn surrounded by an area of intensely-congested tissue. The skin over the whole of the diseased area is tense, and from the ulcerating points a thin watery exudate usually escapes.

With the decline of the fever there is a diminution in the intensity of the local reaction, so that after two to three days the reddening and swelling have usually disappeared. The ulcerated spots and the parts from which there had been an exudation are now covered by a brown crust, and over the smoother portions of the diseased area small, loose, scaly patches may be seen.

It is important to observe that very small, isolated patches of lupus tissue, the presence of which may not previously have been observed, are frequently rendered apparent through the alterations which the agent effects.

Probably the most conspicuous feature in the action of the agent is its affinity for tuberculous tissue. Not uncommonly there appears after the first or second injection, hitherto unsuspected localized areas in the lungs which present physical signs not distinguishable from those accompanying small areas of tubercular infiltration.

In two cases which came to my notice I saw this result follow the injections. These patients were selected with great care as "control-cases." Their lungs were carefully examined, and from physical signs (no expectoration being present) tuberculosis was excluded. After the first injection there appeared in the apex of the right lung in the one, and in the apices of both lungs in the other, a condition which gave all the characteristic signs of incipient tubercular infiltration.

In certain cases in which there has been much loss of tissue, and in which the vessels of the lungs are exposed and their walls weakened, hæmorrhage is not an uncommon accompaniment of the intense congestion brought about in the vessels of the diseased area.

Of the rarer complications may be mentioned icterus of a hæmatogenous nature, temporary albuminuria, and diarrhœa in children.

To summarize then the conclusions which I was led to draw from the cases seen by me, it may be said:

(1) That the outlook in cases of surgical tuberculosis is good, particularly in those in which the disease is most superficially located.

(2) In the lung cases the outlook seems to be fair if the cases are treated sufficiently early. For advanced cases I think it would be premature to do more than speculate, in view of the existing evidence.

(3) The intestinal cases, so far as they have been observed, are unpromising.

REVIEWS.

DUST AND ITS DANGERS. By T. MITCHELL PRUDDEN, M.D. New York: G. P. Putnam's Sons, 1890.

OUR rapidly-increasing knowledge concerning the growth of the lower forms of life and their relation to disease has rendered it necessary that the profession should have some small book which they can place in the hands of their patients when inquiries are made as to the care which should be taken in regard to the inhalation of dust of various kinds.

Dr. Prudden's book possesses two advantages: It is written in a popular vein, and yet does not descend in the least to the informalities which so frequently mar medical books for popular use. The other advantage which it possesses lies in the fact that its author is one who, from his close study of the subject, is quite as well qualified to write a book for the profession as for the laity, and his statements are to be received in consequence with the fullest confidence.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, December 4, 1890.

J. EWING MEARS, M.D., IN THE CHAIR.

DR. DE WILLARD FOREST reported the following case of

TREPHINING OF THE SKULL: OTITIS MEDIA: TUBERCULAR MENINGITIS.

M. K., aged four years, of healthy parentage, without ascertainable tuberculous taint from parents or grandparents, all of whom are living.

At the age of eighteen months she had an attack of pneumonia, which, however, left no impairment of the lung. Had suppurative otitis at the age of two and a half years. At the age of three years she had erythema nodosum on the anterior part of the legs. Three months ago she had an attack of diphtheria, followed by right cervical adenitis, which did not advance to suppuration, and the induration nearly disappeared after a few weeks at the seashore.

About this time the right ear, which had discharged for two months one year previously, showed a few drops of offensive pus oozing from the meatus daily. The child's general health was excellent, and all her hygienic surroundings were good.

The only known injury of the head was a fall from a bed about six weeks previously, but the blow was not even sufficient to arouse her from sleep. The weather, early in May, 1889, was unusually hot, and the child complained greatly of the sun. Previously she had been quiet and cheerful, but at this time she became peevish, irritable, and sleepy. The temperature was normal, the pulse 90.

When seen by Dr. Shellenberger, her tongue was heavily coated and stomach irritable. Vomiting had occurred on two or three occasions, but was at once controlled by the use of peptonized milk, and it never recurred. There had been no constipation, and the bowels were easily moved by one dose of calomel and compound liquorice powder, and all through the course of the disease there was no further constipation. There was pain at the top of the head only, and her cries were fretful rather than shrieking.

A week later when Dr. Willard saw the patient with Dr. Shellenberger, there had been no recurrence of the vomiting or constipation. There was no crying out, only an increase of mental heaviness and an indisposition to be disturbed. There was considerable pain at the top of the head, but there had been no convulsions, strabismus, twitching, or rolling of the head. Her only expression of pain was, "My head hurts me so." Her countenance was placid and without a frown. Under the use of bromides and iodides, with calomel, there was slight failure during the next few days, with increasing stupor and marked loss of strength. Her head was shaven and iodoform ointment applied to the scalp. There was no paralysis and the control of the sphincters was never lost. The pulse was less than 100 and the temperature 99°. The stupor steadily increased.

By the eleventh day from the onset of the disease the patient had become absolutely unconscious; she was unable to swallow; the stupor increased and death was imminent. The slight discharge from the right ear furnished the only indication for even a possibility of relief by surgical means, but as the membrana tympani was found to be perforated, as ascertained by passing water through the nose from the auditory canal, it was decided to give the child her only chance, in the face of rapidly-approaching death, by attempting to reach any possible focus of meningeal irritation that might exist. There was no œdema and no tenderness over the mastoid. The only hope of avoiding speedy death seemed to be in reaching a collection of pus that might exist over the petrous portion of the temporal bone. The undoubted evidences of otitis media, of long standing, made such a collection possible.

Dr. Agnew was called in consultation, and he fully agreed as to the justifiability of the attempt, since the child was dying and no medical measures offered any possibility of relief. It was thought that relieving pressure on the brain by removal of serum or pus might yield temporary benefit at least.

Operation, May 27, 1889: The shaven scalp was rendered thoroughly antiseptic, and the instruments, as well as the hands of the surgeons, were similarly treated. The scalp was raised by a semicircular flap, with the base upward, three-fourths of an inch above the summit of the right auditory meatus and an equal distance behind it. A point as the centre of the proposed opening in the skull had been marked with a drill, and this brought the opening well above the lateral sinus. A three-quarter-inch trephine was used. The skull was so thin that it required great caution in the use of the instruments, and only a few turns of the handle of the trephine were made before the dura was reached. This extreme thinness of a child's skull should be carefully considered in all trephining operations. The button which was removed, and which Dr. Willard exhibited, is almost thin as paper.

On opening the dura, there was marked bulging into the opening, but no signs of pus were present. The arachnoid was congested and opaque at various points, but nowhere presented any pathological appearance. An exploring-needle was passed its entire length into the substance of the brain in the direction of the petrous portion of the temporal bone, and in six other directions, but each time failed to disclose any pus. The opening in the skull was enlarged by rongeur forceps until it was one inch in diameter, but no pus could be reached. There was considerable oozing of arachnoid fluid. By avoiding the spaces between the convolutions in the different punctures the hæmorrhage was slight, and no ligatures were required throughout the operation. No signs of injury or depression were found.

The dura was sutured in position with catgut, and the flap was loosely stitched. As the object was to relieve pressure the bone was not replaced, although it had been carefully preserved in a warm antiseptic solution. Catgut drainage was used, and thoroughly antiseptic dressings were applied.

The child rallied well. The temperature several hours later was 102°, the pulse varied from 100 to 140, and the respirations were 38. The child aroused decidedly, although she did not become fully conscious. Swallowing, which had been impossible before the operation, was now accomplished with ease, and the stupor was much less marked.

From the copious notes taken by the attending physicians and two skilled nurses in regard to the progress of the case, Dr. Willard read the following extracts.

There was no vomiting; the bowels were moved two or three times daily, and peptonized milk was well borne. Urine was passed freely at all times, but never unconsciously until within the last forty-eight hours of life. Bromides, iodides, and calomel were continued. The pulse on the first day was 132, respirations 36, temperature 100°. On the evening of the second day the temperature rose to 102°. On the morning of the third day it had fallen to 99°, and rose again in the evening to 101°. On the following morning it had fallen to 98.8°, at which time the pulse was 100 and respirations 28.

Up to this time the child has been doing exceedingly well, but in the afternoon of the third day the temperature rose to 102°, with increased restlessness and weakness. The wound was, therefore, opened. The flap had thoroughly united, except at the point of emergence of the catgut drain, where a drop of pus apparently indicated an accumulation beneath. A portion of the flap was accordingly forcibly re-elevated, but no pus was discovered. This action, the speaker now thinks, was an error. The wound was healthy, and there was no redness or signs of inflammation. A small rubber drainage-tube was inserted beneath the flap, and the under surface of the flap was washed with 1-to-4000 sublimate solution. Consciousness returned to a slight degree after this. On the third day the patient easily turned on her side and slept quietly most of the time. Respiration was moderately rapid, and although not fully conscious she was cognizant of surrounding events.

On the fourth day the temperature rose to 102.4°, reaching 100° as its lowest point during the day. The pulse was 124, and respirations 40. The child had convulsive movements and became much weaker. The convulsions increased in severity and frequency until the fifth day, and, at times, continued from thirty to forty minutes. The face was flushed; respiration urgent and jerky, with much rattling of pharyngeal mucus. The right thumb was firmly flexed on the hand, and the fingers were rigidly flexed. The elbow was rigidly extended, and the right arm moved convulsively. The left arm was almost constantly in motion with the following rapid series of movements: First, the thumb was flexed, then the fingers; then there was strong and excessive pronation. Instantly the arm was then carried outward and upward with a circular movement, then downward along the side of the head, over the ear, and down the anterior part of the chest, thus describing a perfect circle, the forearm being largely in a position of pronation. This rolling movement was repeated fifteen to twenty times, when there would be a cessation of from five to ten minutes, sometimes of sixty minutes. On account of the continuance and character of these muscular movements, Dr. Horatio C. Wood was called to see the patient in consultation to ascertain if any definite focus of irritation could be reached. The knee was bent and a restless kicking motion was kept up for from five minutes to an hour; only occasionally would there be quiet sleep. The pupils were slightly dilated, and there was no strabismus. The left pupil did not respond to light, and the right but slowly. There was slight frothing from the mouth. The pulse was feeble—110—and sometimes was lost at the wrist. The temperature was 103.2°. When the wound was opened a small hernia cerebri was found, and some softened cerebral substance escaped, but there was no pus. The hernia cerebri increased in size, and there was oozing of softened cerebral tissue. During the dressing one or two vessels bled freely, but the hæmorrhage was controlled by hot water. A finger was carried into the opening in the skull and cautious investigation was made downward toward the petrous portion of the temporal bone, but no pus was found. Nitrite of amyl controlled the convulsions slightly. Under the influence of bromide and chloral the convulsive movements had lessened, save those of the fingers, which were rigid and permanently fixed. The fingers of the right hand were less rigid than those of the left hand. The right leg was flexed at the knee and restless.

An exploring-needle was passed into the brain-substance toward the centre, from two positions, but no pus was found. The convulsions were less severe than in the morning, and deglutition, which was then impossible, was now easily performed. The face was colorless and pallid, and respiration had almost ceased. The pulse became weak and feeble, being about 200 a minute, and the child died on the following day, six days after the operation.

Post-mortem examination nine hours after death: At the site of the operation there were no signs of pus, but there had been sufficient loss of cerebral substance to make a cavity beneath the opening in the skull. The brain-tissue surrounding this was softened, but not purulent. There was much congestion of the meninges, evidently from local cerebritis. Scattered over the membranes, at various points, but especially over the base of the brain and the medulla, were disseminated points of tubercle, some of them the size of pin-heads, but there

were no deposits on either cerebral hemisphere, or in the longitudinal fissure. There were no indications of cerebritis, except the congestion surrounding the wound. There was no pus in any portion of the brain. Neither the petrous nor the mastoid regions showed any evidences of inflammation or disease. The symptoms were evidently due, therefore, to tubercular deposits; yet the ordinary symptoms of tubercular meningitis were almost absent throughout the entire course of the disease. The local cerebritis surrounding the site of the operation showed that the procedure had not been a harmless one, although done on the strictest antiseptic principles. Death was probably delayed five or six days by the operation.

The operation of trephining was undertaken as an almost hopeless attempt to discover some possible cause of the meningitis. The child was rapidly approaching death, and medical measures offered no hope. The existence of long-standing otitis media rendered the presence of temporal osteitis very probable, although there had been no symptoms of mastoid disease. The patient's life was undoubtedly lengthened a few days by the relief of pressure, and in the almost entire absence of any symptoms indicating tubercular meningitis it was not strange that the physicians should have searched most earnestly for some acute exciting cause of inflammatory trouble.

In the present condition of brain surgery it is wise, Dr. Willard said, to report all failures as well as successes, in order that the accumulated evidence may finally give us the proper limitation for operative interference for disease within the cranium.

In discussing this paper, DR. JAMES COLLINS said that he was much pleased to hear the report, and thought that in many cases of ear disease such an operation would be proper. He has performed one or two similar operations, but in traumatic cases. He operated in a case of hæmorrhage, and removed a clot which was pressing upon the brain; the patient recovered. But whether brain surgery will enable us to anticipate the ravages of tubercle is still a question.

DR. JOHN B. DEAVER said that the piece of bone exhibited was certainly very thin, and, in contrast with this, he mentioned the case of a child with an intracranial aneurism of the arterio-venous type which he recently operated on, and in which the skull was quite as thick as an adult skull.

The diagnosis of brain-abscess, he said, is certainly often difficult. He recalled the case of a child who, while throwing an umbrella into the air, was injured by the end of one of the ribs entering the nostril and fracturing the ethmoid bone. Symptoms developed pointing to brain-abscess. The patient was trephined, but no abscess was found. A second operation was also done without finding the abscess. The autopsy showed a large abscess in front of the fissure of Rolando, with a sinus extending to the wound in the nostril. He could readily see how a case of tubercular meningitis with anomalous symptoms might lead the surgeon to suspect abscess resulting from ear disease.

In closing the discussion, DR. WILLARD said that, as stated in the paper, the operation was undertaken as the only possible means of saving the child's life. The presence of suppuration of the ear for two years, with perforation of the membrana tympani, gave the only possible clue to a surgical cause. There were no evidences of mastoid disease, but there was a possibility that the petrous portion had been perforated, and that a collection of pus had formed at this point, or that the meninges were becoming congested. There was such an entire absence of the ordinary symptoms of tubercular meningitis that he did not believe that tubercular deposit was present until the post-mortem examination revealed it.

DR. THOMAS G. MORTON then reported a case of

CONGENITAL (DOUBLE) EQUINO-VARUS, WITH EXCISION OF BOTH ASTRAGALI,

and exhibited casts, photographs, specimens, and patient. Linton B., aged eleven years, from Towanda, Pa., was brought to the Orthopædic Hospital, October 10, 1890, with talipes equino-varus—complicated variety.

History: At birth both feet were greatly distorted, and when a few weeks old tenotomy was performed and a plaster dressing applied. All treatment was abandoned at the end of a year, although the deformity had not been improved. At two years of age the child attempted to stand, but from that time to the present he has been unable to walk or even stand without some support.

On examination the limbs were found poorly developed, muscles greatly atrophied, feet rigid and could not be brought to a right angle with the leg. The astragalus was displaced forward. There was contraction of all the flexor muscles.

On October 16th, an incision was made from the external malleolus to near the base of the metatarsal bone of the fourth toe. The astragalus was found in front of the tibia and fibula and was subcutaneous; its presence in this position rendered flexion of the foot impossible. It was readily excised. The tendo-Achillis as well as the flexor tendons of all the toes was cut, and in the right foot the plantar fascia was divided. No vessel required ligation. A catgut drain was inserted, and, after the usual dressings, a right-angled tin splint was applied.

Four weeks subsequently the dressings were removed, when the wounds were firmly closed, and the lad was allowed to walk. On the thirty-fifth day he walked nearly a mile with no inconvenience.

In connection with this report Dr. Morton read the following letters—one from Dr. Hunt, the other from Dr. Forbes:

"PHILADELPHIA, October 16, 1890.

"To-day I was present at an operation for the removal of both astragali from the feet of a boy about eleven years old, for intractable club-foot when treated by ordinary methods. The operator was Dr. Thomas G. Morton; Dr. W. S. Forbes was also present. Dr. Morton was particularly desirous of the presence of Dr. Forbes and myself, as the necessity for this apparently serious operation has been questioned. I had seen it performed on very young children with favorable results, but as the displaced bones had nothing about them recognizable as astragali, I was anxious to have an older patient to examine in order to observe the effects of development in the abnormal position. That there was nothing normal recognizable in the cases of the young infants I

speak of is proved by the fact that, on one occasion, both bones were removed and were sent to that profound anatomist, Dr. Joseph Leidy. He did not know them, or even whether they were human. This is important, as bearing upon the fact of regarding them surgically in these cases as foreign bodies.

"In the case of the patient operated on to-day the deformity characteristic of a displaced and abnormal astragalus was particularly noticeable in both feet. In front of the external malleolus there was a marked projection more than one-half an inch in diameter, which, when covered by the skin, seemed both to sight and touch like the head of some displaced bone. The normal depression across the natural foot at this place was wanting, and the projecting bone made full flexion impossible. There were the usual callosities found on the feet of active boys of this age who have been afflicted with club-foot from birth.

"The boy was etherized and the bones were removed through one long incision in each foot. The Achillis tendons were divided, and, in one foot, it was necessary to divide the plantar fascia subcutaneously. The wounds were sutured, and the feet were easily brought into the right-angled position and secured upon tin splints.

"The removed bones were now examined. As in the young infant, there was little resemblance to normal bones, but there was enough to recognize what they were. One of them is sufficient for description: In the first place, it was abnormally long, and much the greater portion of it was in front of its true position. It was bent upon itself, and, as it were, partially rotated inward. The bending was across the body of the bone, and the above-mentioned peculiar projection in front of the external malleolus was the anterior lateral portion of the external face of the astragalus, which is normally marked by the articulating facet for the external malleolus. The true articulating facet was only partially formed. The neck and head of the bone projected obliquely across the foot from without inward. The bone seemed to have no support from the sustentaculum tali, but as the object was to save the foot this could not be positively ascertained; nor could the effect of the displaced bone upon the rest of the tarsus, for the same reason, be looked into. Sufficient, however, was found to demonstrate that in this class of cases of club-foot, the astragalus is not only useless, but very harmful. It is practically a foreign body, and should therefore be removed. Without its removal the sole of the foot cannot be brought to the ground, because the foot cannot be flexed to a right angle, as the displaced bone is a complete check to the joint. WILLIAM HUNT."

DR. FORBES wrote:

"The astragalus was displaced outward and forward, its long axis diagonally across the external dorsal aspect of the foot. Its interior posterior margin was placed in front of, and articulated with, the external malleolus (the fibula). The os calcis, the long axis of which is normally quite in accord with the long axis of the foot, had its long axis thrown from behind forward and outward and nearly at a right angle with the astragalus, as the latter was found as stated above. The outer margin of the whole foot was turned inward; the plantar aspect of the whole foot faced the foot on the opposite side.

"In the production of this astragalus-displacement all the flexor muscles have been more or less involved, the flexor communis the least."

DR. MORTON also exhibited another case illustrating severe congenital equino-varus. The girl, eleven years of age, was recently admitted into the Orthopædic Hospital, and was presented for inspection in order that the deformity of her foot could be compared with the deformity shown in the casts, taken before operation, of the feet of the boy previously exhibited. In the case of the girl there was no displacement of the astragalus, but the deformity was due to distortion of the soft parts, which can be cured by section of those tissues. The case was one of *uncomplicated* equino-varus, for the tarsal bones were normally situated, the intra-uterine paralysis having occurred late in gestation; while the first case was a *complicated* equino-varus, with displacement of the astragalus, which required excision of that bone. In the latter the paralysis occurred early in fœtal life, and the flexor muscles, by long-continued traction, forced the astragalus forward and inward, and entirely away from its normal position.

In the uncomplicated deformity, division of contracted tissues is all that is required; in the complicated, the astragalus must always be removed.

DR. MORTON then showed a

LARGE CALCULUS REMOVED BY SUPRAPUBIC CYSTOTOMY.

The calculus weighed 940 grains. The patient was sixty-five years of age, and had been suffering from inflammation of the bladder, with symptoms of stone, for many years. After the operation a soft catheter was retained in the bladder, as well as a rubber drain in the wound.

DR. WILLIAM G. PORTER exhibited a

DRESSING FOR FRACTURE OF THE CLAVICLE,

applied to a patient.

The dressing was devised by Dr. Arthur E. Spohn, of Corpus Christi, Texas. Dr. Porter thought that it carries out the indications in the treatment of this common accident better than any dressing with which he is acquainted. The dressing consists of an anterior splint formed of a piece of barrel-hoop, which is padded, the padding being thicker at the two extremities. The shoulder is drawn upward, backward, and outward, and the deformity reduced. The splint is then applied to the front of the chest and held in place by a posterior figure-of-eight bandage of the shoulders. All the crossings of the bandage are secured by stitches. The dressing is simple and cheap, and has the advantage of leaving both arms free. The only objection to it that Dr. Porter has noticed is that, if the bandage is applied tightly, it will cause swelling of the arms from interference with the circulation. In the case exhibited, the fracture occurred two weeks previously, and was the only case of true fracture of the clavicle that the speaker had seen since he became familiar with the dressing. He has also used it in one case of green-stick fracture of the clavicle, with satisfactory results.

In discussion, DR. MORTON said that experience might demonstrate that the apparatus exhibited is a useful dressing in certain cases of fracture of the clavicle. In all fractures of this bone it is safer to keep the patient

for at least a week or two in the recumbent position. In oblique fractures, he thought that the apparatus exhibited would be hardly sufficient to retain the fragments in position.

DR. JOHN B. ROBERTS said that it seemed to him the principal element in the treatment of fracture of the clavicle is fixation of the inferior angle of the scapula. He feels that in these cases the scapula must be rendered immovable, and kept so either by putting the patient on his back in bed, or by the use of some of the methods of making pressure upon the lower angle of the scapula that have been suggested. He could not see how a figure-of-eight of the shoulders with the anterior extension-splint pressing upon the deltoid muscles over the head of the humeri, can make enough pressure to prevent the scapula from slipping out toward the axilla and causing overlapping of the fragments. As he placed his hand on the clavicle in this case, he noticed considerable deformity, but whether this was due to overlapping or to callus he could not say.

DR. WILLARD noticed that as the man took off his shirt and replaced it, he moved his arm very freely and without the least expression of pain. The speaker never before saw a patient do this with so much ease at the end of two weeks after a fracture of the clavicle.

DR. PORTER thought that if anyone would make the experiment of having the shoulders drawn upward, outward and backward and secured with this dressing, they would find that it makes considerable compression and holds the shoulders firmly in position. As he had stated, he had had no extended experience with the appliance, but it seems to fulfil the indications very well.

(To be continued.)

CORRESPONDENCE.

TREATMENT OF ECTOPIC PREGNANCY.

To the Editor of THE MEDICAL NEWS,

SIR: Dr. Baldy's article on the treatment of ectopic pregnancy, which appeared in the last number of THE MEDICAL NEWS, contains two references to my work, which, as usual, are more or less glaringly inaccurate. In reference to Dr. Morris J. Lewis's case, he states that "a growing tubal pregnancy" was removed by Dr. Penrose, the truth being that a dead and partly macerated fœtus was removed. The other reference appears under the heading: "The harm done [by elecricity] in case of a mistaken diagnosis," and as it is the only instance of such "harm" cited by him, its flimsy character disposes of the claim. He here states that Dr. Bradford reported a case of mine in which two applications of electricity were followed by "alarming illness." The case was not reported by Dr. Bradford, but by myself, in the chapter on "Contra-indications" in my work on *Electricity in the Diseases of Women*. At the operation, which was followed by a fatal result, a malignant cyst of the broad ligament was discovered. The third error was in saying that this case was made any worse by the treatment, beyond a mere aggravation of the pain, which led me to examine more closely, and discover a cystic condition. The fourth error was in alluding to this case at all, which received intra-uterine applications, when he states, at the beginning of the article, that only the approved methods of passing the currents through the sac will be considered. In such methods the internal electrode is invariably placed in the vagina.

Yours truly,

G. BETTON MASSEY, M.D.

212 SOUTH FIFTEENTH STREET, PHILADELPHIA

IDIOSYNCRASY TO THE EXTERNAL APPLICATION OF IODINE.

To the Editor of THE MEDICAL NEWS,

SIR: In the Surgical Ward of the German Hospital, in the service of Dr. Deaver, there recently occurred a case of extreme idiosyncrasy to iodine.

The patient, an adult, suffering from osteitis of the cervical vertebræ, was painted with tincture of iodine just below the mastoid process over an area three inches square, only one application being made. Almost at once the patient complained of tingling and burning sensations over the whole body, and in less than three minutes the skin was everywhere covered with an intense erythematous rash. The patient now complained of ringing in the ears, throbbing in the head, and palpitation, and became very anxious. His temperature, half an hour after the application, was 96¼° F., his pulse was 66. Respiration was normal. His lips were somewhat cyanotic in appearance. The rash began to disappear in the course of an hour. The eyes began to "water," and the lids were very much congested, as well as the conjunctiva and the eyeball. There was no vomiting or sneezing at any time. The region on which the application was made became much swollen. The temperature two hours after the first symptoms appeared was 100°, and the pulse at the same time 96. The eruption had entirely disappeared in three hours, although the conjunctiva remained reddened. The urine, examined half an hour and three hours respectively after the application, gave no reaction to the ordinary tests for iodine.

The patient gives a history of a similar experience some years ago after an external application of the tincture of iodine. Iodide of potassium had been administered to him in small doses for many weeks without the occurrence of bad symptoms.

The only treatment was the removal of as much as possible of the iodine that remained on the skin, and stimulation.

At the present writing, twelve hours after the occurrence, no symptoms of the intoxication remain.

M. V. BALL, M.D.,
Resident Surgeon.

KOCH'S METHOD AT ASHEVILLE, N. C.

To the Editor of THE MEDICAL NEWS,

SIR: At the present time it may not be out of place to report unfinished cases subjected to the new method of treatment for tuberculosis suggested by Professor Koch, and to state its effects as far as observed.

I began to use the method here immediately upon my return from Berlin on December 23d. Thus far, eleven cases have been treated by me at my private institution for diseases of the lungs and throat, and one case at the Mission Hospital in this city.

Of the eleven cases five had, besides the pulmonary affection, tubercular deposit in the larynx; in two of these, ulcerative processes existed, and the lung disease was beyond what may be called an early stage. Five other cases are in an earlier stage of pulmonary tuberculosis; the eleventh case is one of lupus vulgaris of ten years' standing, with progressive destructive tendencies.

The case at the Mission Hospital is also one of lupus that has lasted thirty-five years and is very severe, involving extensive portions of the nose and face. All cases are in fair physical condition and bear the reactions well.

Without going into the details of each dose, with its accompanying reaction, I have begun with only three-tenths of a milligramme for the initial dose in cases in which the larynx is involved, and in all but one case the reaction was well marked. In one case it was quite serious, inasmuch as so much swelling occurred in the larynx that the respiration was considerably impeded for several hours.

In the purely pulmonary cases the usual beginning dose of 1 milligramme was used; of these, one case has shown no reaction yet, 4 milligrams having been reached at the present time; in the meantime the expectoration is loaded with tubercle bacilli.

All these cases show more or less improvement; especially is this manifest in the larynx, where diminution of the infiltration and tendency to repair are unmistakable.

Increase in the moist sounds in the lungs, or an appearance of such where previously absent, has been quite constant during the reaction and for a day or two thereafter.

In the cases which have received the treatment for two weeks or longer there is evidence of other improvement, especially in the general condition of the patient; none are losing in weight, and several are gaining quite perceptibly.

In the pulmonary cases, after reaction, several days' intermission of the treatment is given, to allow them to recuperate fully, during which time the climatic treatment is carried out as before.

The lupus-patient at the Mission Hospital is doing very well, the ulcer is healing from the edges and granulation of the deep cavities has commenced. The upper lobe of the right lung in this case showed symptoms of infiltration, with cough and bloody expectoration, after the third injection of 10 milligrammes. No evidence of pulmonary disease existed before the treatment. In the lupus case in my institution the reaction is intense after one milligramme, and accompanied by an intense scarlatinous rash all over the body.

So far, then, the results are very satisfactory indeed, and with the advantage of climate as well we hope to be able to show all that is possible to accomplish under the most favorable climatic condition with strict and painstaking management in a special institution by the new method, which is now the absorbing theme of medical men and the public in general, even at this remote region.

Very respectfully,

KARL VON RUCK, M.D.

ASHEVILLE, N. C., January 10, 1890.

To the Editor of THE MEDICAL NEWS,

SIR: My attention has been called to the announcement of Mr. F. A. Davis, a publisher of Philadelphia, who claims to have in press the second volume of a work entitled "A Treatise on Materia Medica, Pharmacology and Therapeutics," my name being used as joint author with Dr. John V. Shoemaker. I desire to say that the use of my name in connection with Vol. II. of this work is unauthorized, and without my consent, and I am credibly advised that such publication can be restrained by legal means. For good and sufficient cause, my association with the publisher and reputed author was severed months ago, and of this, intending purchasers will take due notice. Very respectfully,

JOHN AULDE, M.D.

1910 ARCH STREET, PHILADELPHIA.
January 5, 1891.

NEWS ITEMS.

New York State Medical Association.—The Seventh Annual Meeting of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn on Tuesday, May 26, 1891. All Fellows desiring to read papers will please notify the Secretary, E. H. Squibb, M.D., P. O. Box 94, Brooklyn.

Decrease of Insanity in 1890.—In New York State a considerable decline in insanity is indicated by the annual report of the Commissioners in Lunacy, just made to the Governor for the year 1890. The total number of reported cases was 523, as against 598 during the year previous, a reduction of more than twelve per cent.

The cities of New York and Brooklyn furnished about fifty per cent. of the new cases, and it is noted in the report that the decrease in insanity, in the two cities named, has been much more marked than in the other parts of the State. The ratio of new cases to population is constantly decreasing in the two cities; the same seems to be true of the State at large, but in a less marked degree. The report further shows that about sixteen hundred insane are at present in the State hospitals under the management of the Commissioners.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 6 TO JANUARY 12, 1891.

By direction of the Secretary of War, JAMES P. KIMBALL, *Major and Surgeon*, is assigned to duty at Fort Supply, Indian Territory, in Special Orders, No. 132, September 24, 1890, Department of the Missouri.—Par. 6, *S. O. 4, A. G. O.*, January 6, 1891.

By direction of the Secretary of War, CHARLES SUTHERLAND, *Brigadier-General and Surgeon-General*, will, as soon as practicable, repair to this city, and assume the duties of his office.—Par. 9, *S. O. 2, A. G. O., Washington, D. C.*, January 3, 1891.

APPOINTMENT.

SUTHERLAND, CHARLES, *Colonel and Surgeon.*—To be Surgeon-General, with the rank of Brigadier-General, December 23, 1890, vice Baxter, deceased.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 10, 1891.

RUTH, M. L., *Surgeon.*—Ordered to the U. S. S. "Newark," February 2, 1891.

RUSH, W. H., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Saratoga," and ordered to the U. S. S. "Newark," February 2, 1891.

III.

THE COMPOSITION OF THE FLUID OF DIXON.

VIRCHOW ON THE INJURIOUS EFFECTS OF KOCH'S METHODS.

At the Berlin Medical Society on January 7th, Professor Virchow exhibited specimens from twenty-one patients treated by Koch's method who died before January 1st. Since then six or seven more necropsies had been made by him and specimens from these were also shown. Of the former series, sixteen were cases of phthisis.

Professor Virchow illustrated the irritating effects of the fluid by the specimen of a brain removed from a child with tuberculous arachnitis, who died after four injections of the lymph amounting in all to two milligrammes. There was intense hyperæmia of the brain and pia mater such as Professor Virchow had never before seen. The vessels of the pia were extremely engorged and the brain-substance internally was of a dusky-red tint. The speaker could not see any signs of retrogressive metamorphosis of the tubercles. Acute hyperæmia and swelling were also seen in the internal organs of other cases. The walls of old cavities in the lungs showed unusual redness of the granulations and recent hæmorrhages. In one case hæmoptysis from an old cavity was the immediate cause of death.

Virchow says there can be no doubt that in internal organs acute inflammation and active proliferation are set up by injections of the fluid. These conditions are seen particularly in the edges of tuberculous ulcers and in neighboring lymphatic glands, especially the bronchial and mesenteric glands. These glands swell to quite an unusual extent and rapid proliferation of the cells in their interior takes place. The colorless elements of the blood are increased and a condition of leucocytosis is established. In the larynx, even when the surfaces of the ulcers become clean, swelling of the adjoining parts may be dangerously great. He showed a recent specimen in which erysipelatous-like œdema of the glottis and a retro-pharyngeal

phlegmon had been produced. The changes in the lungs consisted in caseous hepatization, of which an extreme example was shown.

This condition existed in five out of the sixteen cases of phthisis, associated with a special form of pneumonia, resembling the catarrhal type, but differing therefrom in the character of the secretion. The lungs in some places presented foci of softening, and even cavities, the result of acute inflammation caused by the injections of the lymph.

The *most important effect observed, however, was an eruption of fresh crops of tubercles after the injections.* This occurs especially in the pleura, pericardium, and peritoneum, and Virchow says that in the case of these serous membranes the statement that the substance of the tubercle is destroyed by the remedy is not confirmed by his examinations; he adds that if the effect of the remedy is to cause breaking down, the result would be to release the bacilli and give rise to new foci of tuberculous disease in other parts of the body by infection with the products of disintegration. Virchow, therefore, urges the greatest caution in the use of the remedy. While admitting that in many cases the lymph does produce the effects claimed for it, he points out that this result is not constant, and he cites cases in which large masses of tubercle were entirely unaffected by injections. He also showed specimens in which perforation of the intestines had been caused by the treatment, and one case of tuberculosis of the larynx in which fresh and extremely intense eruptions of tubercles had taken place throughout the whole extent of the larynx and trachea.

January 14th. Before the Berlin Medical Association to-day Prof. Virchow resumed his lecture on the subject of cases which have resulted fatally after the inoculations of the Koch remedy. He said that he was not prejudiced against the remedy; he simply wished to give warning regarding its too general application. In the discussion which followed, Professors Fränkel and Baginsky spoke in support of Professor Virchow's contention that tubercular disease was sometimes transferred to sound organs by inoculation. Numerous patients in Vienna, after reading the views expressed by Professor Virchow, declined to submit to further treatment by the Koch method.

ABSTRACT OF A THIRD COMMUNICATION ON A REMEDY FOR TUBERCULOSIS.[1]

BY PROFESSOR ROBERT KOCH.

As long as the only point of importance was to judge of the correctness of my statement it was not essential to know what the remedy contained and what its origin was. On the contrary, it was clear that subsequent experiments would be all the more unprejudiced if nothing was known of the remedy itself. I think the right moment has come to make the statements which follow.

If guinea-pigs be inoculated with a pure cultivation of tubercle bacilli the wound closes over with a sticky exudate. After ten to fourteen days a hard nodule presents itself, which, soon breaking, forms an ulcerating sore, which continues until the animal dies.

Quite a different condition of things occurs when a guinea-pig already suffering from tuberculosis is inoculated. An animal successfully inoculated from four to six weeks before is best adapted to this purpose. In such an animal the small indentation assumes the same sticky covering at the beginning, but no nodule forms. On the contrary, on the day following or the second day after the inoculation, the place where the lymph was injected shows a peculiar change taking place at the point of inoculation.

At the point of inoculation and for one centimetre around the tissues become hard and dark. During the next few days it becomes clear that the epidermis thus changed is necrotic; finally, it is thrown off, and a flat, ulcerated surface remains, which generally heals quickly and completely without carrying infection to the neighboring lymphatic glands. Thus the inoculated tubercle bacilli act quite differently on the skin of a healthy guinea-pig than on that of a tuberculous one, but this remarkable action does not belong exclusively to living tubercle bacilli, but also in the same degree to dead ones, whether killed by low temperatures of long duration, which I at first tried, or by boiling heat, or by certain chemicals. Pure cultivations of tubercle bacilli thus killed after they have been ground down and suspended in water, can be injected under the skin of healthy guinea-pigs in large quantities without producing anything but local suppuration.

Tuberculous guinea-pigs can be killed by injec-

---

[1] Deutsche medicinische Wochenschrift, January 15, 1891.

tions of very small quantities—a small dose producing widespread necrosis of the skin. If still more dilute the animals remain alive, and if the injections be continued at intervals of one or two days a noticeable improvement in their condition soon sets in. The ulcer at the point of inoculation becomes swollen and finally cicatrizes. This is never the case without such treatment. The swollen lymphatic glands become smaller and the condition, as regards nutrition, improves. Finally, the progress of the disease is arrested, if it is not already so far advanced that the animal dies of debility. The important thing to be done is to carry out the process which takes place within the body, outside of it also, and, if possible to extract and isolate the curative substance from the tubercle bacilli. This problem required much work and time before I at last succeeded by the help of a 40 to 50 per cent. solution of glycerin in extracting the active principle from the tubercle bacilli.

My further experiments on animals, and finally on human beings, were made with liquid thus obtained, and in this way also the liquid which I let other physicians have in order to repeat the experiments, was obtained. The remedy with which the new treatment of tuberculosis is carried out is, therefore, a glycerin extract of pure cultivations of tubercle bacilli. The constitution of the active principle can as yet be only a matter of conjecture.

It seems to me to be a derivative of albuminous bodies, and to be in close relation to them, but it does not belong to the group of so called tox-albumins, as it can withstand high temperatures, and in the dialyzer passes quickly and easily through the membrane.

The quantity of active principle present in the extract is in all probability very small. I estimate it at a fraction of one per cent.; thus if my assumption be correct, we have to deal with a substance, the action of which on the tuberculous organism far surpasses that of the strongest drugs known.

[The paper concludes with speculations as to the mode of action of remedy in affected tissues.—ED.]

POSSIBILITY OF CHECKING THE TUBERCULAR PROCESS IN MAN BY THE AGENCY OF A METABOLIC PRODUCT OF THE TUBERCLE BACILLUS.

BY SAMUEL G. DIXON, M.D.

IN THE MEDICAL NEWS of October 19, 1889, I called attention to a morphological change of the tubercle bacillus which was different from any that I had previously seen. This change of form suggested to my mind a possible evolution of function, and I realized that it might mean either a greater or less degree of virulence. As a less degree of virulence would be desirable in order to increase the power of animal resistance to pathogenic organisms, I cultivated the bacilli in a number of tubes to the stage at which few or no ordinary rod-formed bacilli could be found in the cultures. When they had arrived at this state of life, I imbedded a mass of the bacilli and débris under the skin of a guinea-pig. The inoculation apparently set up a disturbance in the animal economy. There was a short febrile stage; the lymphatic glands became swollen and the guinea pig seemed to be quite sick. This condition, however, soon passed away and the animal apparently recovered. Immediately after this injection the animal seemed to resist the effects of virulent tubercle bacilli.

In working out the two hypotheses published on October 19, 1889, I became convinced that by treating a mass of tuberculous tissue containing the odd forms of bacilli with some powerful solvent, I might dissolve out a principle that when injected into the animal economy would change the chemical condition of the tissues and thereby prevent the growth of the tubercle bacilli that inhabited the tissues.

To accomplish this, I submitted the tubes containing these actual tuberculous bacillary growths to the action of ether, and also to a saturated solution of sodium chloride. The respective mixtures were then passed through a Pasteur filter without pressure. This active principle, when subcutaneously injected in tuberculous animals, caused a febrile reaction. The tissue in the immediate neighborhood of the tubercles becomes hyperæmic, and the symptoms manifested resemble those produced by the introduction of a portion of the original mass. They also resembled the symptoms said to be produced in tuberculous animals by the introduction of the Koch remedy into the circulation, as well as those produced by the liquid made by Dr. Craft, of Cleveland, Ohio.

A CONVENTION of American physicians interested in electro-therapeutics has been called to meet at the Academy of Medicine, No. 17 West 43d Street, New York, on January 22, 1891, at 11 A.M., for the purpose of organizing an American Electro-therapeutic Association.

MEDICAL PROGRESS.

The Treatment of Chronic Endometritis by Intra-uterine Applications of Boric Acid.—DR. ALEXANDER DUKE (*British Medical Journal*, December 20, 1890) has succeeded in curing a number of obstinate and previously-intractable cases of endometritis by applying pure boric acid to the endometrium. The powder is applied by means of a somewhat curved hard-rubber tube, slightly larger than a No. 12 catheter, and fitted with a piston of the same material. About two inches of the distal end of the tube is charged by plunging it into a deep bottle containing the acid, the piston being withdrawn. The cervical canal is then freed from secretion, the point of the tube is inserted into the uterus, and the acid deposited in the cavity by pushing the piston home. The vaginal walls should be dusted with the powder at the same time. The applications should be repeated at intervals of three or four days.

Treatment of Dandruff.—DR. EDWARD CLARKE (*Lancet*, December 27, 1890) describes the following method of treating persistent dandruff. The method is that practised by Dr. Shudham, and has given excellent results. The head should be well washed with hot water and alcohol soap (pure soft soap, 2 ounces; alcohol, ½ ounce; oil of lavender, 10 minims). The soap is then washed away with hot water, and the scalp thoroughly dried by means of a warm soft cloth. Glycerole of tannin of a strength of from ten to thirty grains to an ounce, according to the obstinacy of the case, should then be well rubbed into the scalp. If tannin fails, resorcin may be used in its place. This process should be repeated once or twice a week. After the dandruff has disappeared the scalp should be rubbed daily with olive oil, containing in each case ten grains of carbolic acid and one drachm of oil of cinnamon.

Treatment of Goitre by Galvano-puncture.—DR. JAMES HENDRIE LLOYD (*University Medical Magazine*, December, 1890) reports four cases of follicular goitre treated by galvano-puncture. The first case was of several years' duration in a woman sixty years old, and was cured by fourteen punctures, each sitting lasting about twenty minutes and the current strength averaging between fourteen and eighteen milliampères. During each application the gland tissue became swollen around the needles, sensitive to pressure, and gas, probably hydrogen, crepitated from within and escaped from the punctures. The surrounding skin was reddened and occasionally the points of puncture were distinctly burned because of defective insulation. For a day or two after the operation the gland would be very sore and on several occasions threatened to suppurate, but this it never did.

The second case was that of a young woman in whom a goitre had been present for about eighteen months. Punctures were made at intervals of a week "for a long while," the current-strength varying from fourteen to twenty milliampères. On one occasion severe inflammation of the gland and of the skin for some distance downward followed. When treatment was stopped the gland was shrunken, hard and gristly, and has remained so for three years.

The third case was not so satisfactory, partly at least because the goitre was an enormous one of many years' standing, bulging on each side and reaching almost to the ears. Very large veins ran over the surface and through the gland structure. The patient discontinued her visits before the results of treatment could be determined.

The fourth case declined to submit to treatment after the first application of the needles.

The apparatus used for the punctures consisted of three small gold-plated needles insulated to within one-third of an inch of the point. These were connected by a branching cord, so that all could be attached to the negative pole of the battery. The method of operating was as follows: The needles were inserted into the tumor far enough to protect the skin by the insulating material, care being taken to avoid veins. The positive pole was connected with a large, flat, sponge electrode. Thus resistance was reduced as much as possible and a strong current made possible without too much pain. But even with this precaution the skin under the sponge became at times much reddened, and in one instance blisters formed. An accurate milliampèremeter was kept in the circuit and constantly observed, and a water rheostat was used to avoid shocks.

Longevity Among the California Indians.—Dr. Remondino, of San Diego, recently addressed the California State Medical Society regarding the longevity of some of the Indians of Southern California, and although his statements are extraordinary, they are of interest. He states that he has obtained strong evidence that not a few of the Indians pass the age of one hundred years. The Indian village at Capitan Grande contains several women more than one hundred and thirty years old. Dr. Remondino quotes a statement of Dr. Edward Palmer, who for a long time was associated with the Smithsonian Institution, that there lived in Southern California a squaw who was one hundred and twenty-five years old, and that he has seen her carry, tied up in a blanket, six melons for the distance of two miles. Near San Diego there lives an Indian who though bent, wrinkled, blind, and reputed to be one hundred and forty years old, is still quite active and daily makes his way to the beach and along the bed of the creek to search for drift-wood. There is another Indian whose age is believed to be not less than one hundred and fifteen years, who is remarkably active and a great walker, an ordinary journey for him being a walk of fifty miles. Father Ulbach, a missionary well acquainted with the habits of the Indians, says that a more temperate and abstemious class of people does not exist, their diet being almost solely of acorns, flour and water.

Climate is undoubtedly a factor in the production of these long years of activity. Malarial diseases and rheumatism are unknown among the original occupiers of the soil, no land is more free from lung affections, and renal and hepatic disorders are seldom met with.

ORIGINAL LECTURES.

DIGESTION, ASSIMILATION, AND OXIDATION—THEIR NORMAL AND ABNORMAL CONDITIONS IN RELATION TO HEALTH AND DISEASE.

A Series of Clinical Lectures, delivered at the New York Post-Graduate Medical School and Hospital.

BY WILLIAM HENRY PORTER, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY.

LECTURE II.

GENTLEMEN: To-day I show you a case which illustrates more particularly primary gastric indigestion.

Mrs. M. E., aged thirty-five years. Up to ten days ago the patient considered herself perfectly well, when she commenced to have pain and distress in the epigastric region immediately after eating, frequently followed by vomiting of a greenish and acid-tasting fluid. Pyrosis occurs immediately after each meal. Her appetite is capricious; bowels irregular; she has some headache and vertigo; her tongue is large, pale and flabby, and shows distinctly imprints of the teeth. Her pulse is weak, the heart's action slow and feeble, the first sound of the heart being faint and somewhat prolonged. In this case remedies addressed chiefly to the stomach have relieved the more active symptoms. The appearance, however, of the tongue; the condition of the heart; the tendency to headache and vertigo, and the irregular condition of the bowels show quite conclusively that underlying or behind these active gastric symptoms we have grave intestinal and hepatic disturbances which must be overcome if we wish to place our patient in the best possible nutritive condition and prevent a recurrence of the more active gastric disturbances.

At our last lecture we considered the changes wrought upon the food-stuffs while in the stomach, and we are now ready to begin with the changes effected after leaving the pyloric outlet and entering the intestines.

The *first* digestive fluid which gains access to the food-stuffs in the intestinal canal is that secreted by Brunner's glands. These glands, from ten to twenty in number, are situated for the most part in the upper portion of the duodenum, above the entrance of the ductus communis choledochcus and pancreatic duct, and but few are found below these openings. They seem to partake of the characteristics of compound racemose and of compound follicular glands. Their secretion is, comparatively speaking, small in quantity and has not as yet been obtained in sufficiently large amounts to give absolute and positive evidence as to its chemical composition and action, but so far as is known it is strongly alkaline, and thereby helps to reduce the acidity of the food-stuffs as they pass into the intestines. It is also said to contain a ferment which has for its physiological action the liquefaction of proteid substances and their conversion into a diffusible peptone.

The *second* or diastatic ferment converts starch into sugar or glucose, and is said to be the most active of all the sugar-forming ferments found in the animal economy. This assertion, however, must be taken with some reservation on account of the difficulty met with in securing the fluid from these glands. As the result of the action of these ferments a certain amount of the proteids and sugars is converted into diffusible substances, which reduces the amount of work to be performed by the pancreatic and intestinal ferments proper.

The next digestive fluids with which the food comes in contact are those secreted by the pancreas and liver, and for convenience we will first consider the former. The quantity of pancreatic juice secreted in twenty-four hours is about 800 grammes, or twenty-five ounces. It has a very strong alkaline reaction due to the large amount of carbonate of sodium that it contains, which tends to transform rapidly the acid chyme into an alkaline fluid, to convert the proteids into an alkaline albumin, and to place all the food-stuffs in a proper condition to be acted upon by its contained ferments. The pancreatic fluid, as is seen by our table,[1] is credited with containing four well-defined ferments, and one of questionable existence. This questionable ferment is rather the result of the steapsin plus the alkalinity of the pancreatic fluid, which produces emulsification, than a separate ferment.

First, the diastatic or amyloptic ferment has for its physiological function the property of converting all forms of starch, both in the cooked or hydrated state, and in the raw condition into glucose, and in intensity of action it is said to stand second only to the diastatic ferment secreted by Brunner's glands. It is by this diastatic action of the pancreatic fluid that the major part of our glucose is formed from the starches.

The *second*, or tryptic ferment, is a powerfully-erosive agent attacking alkaline albumin in an alkaline medium and converting it first into propeptone, then into albumoses, and finally into a true and diffusible peptone. In this action the proteids do not swell up, gelatinize, and finally become peptones, as in the stomach when acted upon by the pepsin, but the solid proteids are eaten away or eroded, molecule by molecule, until they are finally transformed. In this respect it differs from the peptic action and is very much more powerful, and converts a larger quantity of the proteid substances into peptones. Synchronous with this action numerous by-products are formed, but which have, as yet, become of no practical value.

The *third*, or milk-curdling ferment, attacks the milk which may have passed through the stomach unaffected by the milk-curdling ferment of the gastric secretion, transforming it into a semi-solid and flaky casein to be

[1] See Lecture I.

attacked by the tryptic ferment and converted into a diffusible peptone.

Fourth, the fat-splitting or steaptic ferment is the one by which the various forms of fat are split up into their component parts—fatty acid and glycerin—the former by the further action of the ferment being joined to the sodium bicarbonate of the pancreatic juice, and finally resulting in the formation of a hard soap.

The *fifth* ferment, emulsin, which is questionable, is probably not a ferment, but the emulsifying action of the pancreatic juice is probably due to the combined action of the strong alkalinity of this fluid and the steapsin, on the fats, by which the latter are most perfectly emulsified and placed in a condition in which the epithelial cells can seize upon the minute particles of fat, draw them into the cell-protoplasm and discharge them into the lacteals. This absorption by the epithelium is easily demonstrated under the microscope.

It seems to me quite reasonable to suppose that the protoplasmic substance composing the epithelial cells lining the alimentary tract has for one of its vital properties the power to draw into itself the soluble and diffusible proteids, glucose and salts, and to discharge them into the venous capillaries of the entero-hepatic circulation, and that by this channel they reach the liver. As the proteids, sugars, etc., are in the liquid state we cannot follow the transit through the cells as we can the fatty particles, but reasoning by analogy we may assume that the process occurs. That they do pass to the liver is unquestioned.

The intestinal secretion by this method of tabular arrangement is narrowed down to that fluid which is secreted by the simple follicles and the glands of Lieberkühn. It is, however, from the latter class that the active ingredients or ferments originate. The succus entericus, as you will readily see by referring to our table,[1] is a limited secretion, but still one which in itself contains four active principles.

The *first*, or diastatic ferment, differs from those already described in that it does not form maltose, but converts maltose into glucose, completing, as it were, the diastatic action of the ptyalin and amylopsin. Its action is secondary and somewhat limited.

The *second*, or proteolytic ferment, has for its function the property of converting fibrin into a peptone. The origin of this ferment in the glands of Lieberkühn appears to be somewhat in doubt, being traced by some to Brunner's glands. That such an action is effected by the compound juices of the intestines there seems to be little if any doubt.

The *third* ferment, or invertin, is probably the most important of all the ferments of the succus entericus. Most of the sugar which we take as food is, as you know, in the form of cane-sugar and not glucose, and practically speaking little or no glucose is taken with the ordinary food-stuffs. Another noticeable fact is that few physiologists give us any information regarding the fate of the cane-sugar after it has passed the œsophagus. We are taught that it cannot pass into the blood in its original form, but we are not told that it passes as sugar from the anus; consequently what becomes of the large amount of cane sugar ingested daily was formerly a doubtful question in my mind. But the question is now clearly and satisfactorily explained by this inverting-ferment which changes the cane-sugar into an absorbable glucose.

A *fourth*, or milk-curdling ferment, is also spoken of in connection with the intestinal fluid. Whether this is a direct product of the intestinal glands, or originates from some of the other secretory glands already described, is an undecided question. There seems to be, however, no doubt that when the succus entericus is added to fluid milk it precipitates the caseine, and that if any milk reaches the intestine in a fluid state the caseine is there precipitated and placed in a favorable condition to be acted upon by the peptonizing ferments and converted into a diffusible peptone.

We now come to the study of the most interesting of the digestive fluids, and the one which is least accurately understood, namely, the bile. If viewed from our combined physiological knowledge, and that derived from close clinical observation, we are enabled to speak with a much greater degree of accuracy than can be obtained in any other way. Experimentally, it is almost impossible to prove positively the action of the biliary fluid, for the moment a biliary fistula is established and the bile turned from its natural channel, all the functions of the body are so thoroughly disturbed that the most contradictory evidence is obtained. Nevertheless, the knowledge derived in this way, together with clinical and pathological observations, has enabled us to formulate the following actions of the bile. The ordinary physical and chemical properties need not be considered in detail, as it is the physiological actions which concern us most. These actions are quite numerous and not necessarily due to contained ferments.

First: It has an emulsionizing action, that is, it acts upon neutral fats and minutely subdivides the oil-globules so that they can be easily taken up by the epithelial cells and discharged into the lacteals. It does not appear to have the property of splitting fats into their component parts—a fatty acid and glycerin—but when freely mingled with the biliary fluid, the fat is placed in such a condition that the steapsin of the pancreatic fluid can more easily separate it into a fatty acid and glycerin, and form a soap by the union of the soda and fatty acid.

Second: The bile contains a diastatic ferment which has for its action the conversion of starch and glycogen into glucose.

Third: Taken as a whole, the bile may be regarded as a stimulant, producing peristalsis of the intestines, thus tending to favor absorption and prevent constipation.

Fourth: The bile-acids in particular are stimulants to the small muscles contained in the villi, so that by the contraction of these muscles the contents of the lymph-spaces are emptied toward the larger and deeper lymphatics, leaving those in the villi empty and in a position to absorb more. Regarded in this light the lymph-sacs of the villi are little pumps which are constantly pumping the fat out of the epithelial cells and discharging it into the deeper lacteals to be passed on to the general circulation.

Fifth: The moistening of the epithelial cells with bile seems to be necessary for their vital activity, enabling

[1] THE MEDICAL NEWS, January 10, 1891, p. 31.

them to take up both glucose and peptones much more rapidly than is the case when they are deprived of a free supply of bile. The bile seems also to stimulate a watery flow from the intestinal follicles, which together with its tendency to excite peristalsis favors a free and easy passage of the intestinal contents into and through the colon. By some the bile is spoken of as a lubricant to the colon, which combined with the other effects, favors free movements and prevents constipation.

Sixth: The biliary fluid prevents decomposition in the alimentary tract and may be looked upon as Nature's chief antiseptic. This assertion is sustained by the rapidity with which decomposition occurs whenever the biliary secretion is impaired, totally arrested, or changed in quality. Under these circumstances we notice at once a tendency to persistent constipation, clay-colored stools and the distention of the intestines with gas. If the quantity of bile is abundant, but of poor quality, there is a tendency to black, tarry, and burning stools, with some tympanites, and fermentation and incomplete digestion of the food-stuffs.

Seventh: I think we are justified in assuming that the bile and its contained ingredients aid very materially in the final solution of the albuminoids, and their conversion into diffusible peptones. This view is entertained after a careful clinical study of a large number of cases which has clearly shown that unless the old bile and that of poor quality be expelled from the system, and its place taken by new bile, and that of a better quality, the digestive disturbances cannot be overcome; but that so soon as this change is effected digestion and assimilation become perfect and nutrition is carried on normally. This is conclusively proved by the fact that the products of oxidation found in the urine rapidly change from an excess of uric acid, oxalates, and urates, to urea, carbonic acid, and water.

Having by the action of these various fluids and ferments placed our food-stuffs in a condition in which they can be removed from the alimentary canal, we find the fats going by the way of the lymphatics and thoracic duct to the vascular channel, and thence poured into the blood-current at the junction of the left internal jugular and subclavian vein. From here they pass as fats through the left bronchio-cephalic and superior vena cava to the right auricle on to the right ventricle, and through the pulmonary arteries to the lungs. In the lungs the fat in its original form appears to be acted upon by the oxygen and changed, so that it can no longer be recognized as such in the blood. It yields in its various transformations, heat and energy to the system, lubricates and protects various parts of the body, and is finally eliminated as carbonic acid and water. The sugars and peptones pass by the entero-hepatic or portal system of vessels directly to the liver, where they are variously changed by the hepatic cells and distributed to various parts of the body.

The changes wrought upon the glucose, peptones, etc., are perhaps best discussed under the action of the liver, and may be considered under seven headings:

First: The so-called glycogenic function or action. When speaking of this function it is commonly asserted that the hepatic cells have the property of attacking the glucose, changing it into glycogen, and storing it, then changing it back into glucose to be finally lost in the system and oxidized into carbonic acid and water. This storage-house action of the liver I have never been able to comprehend, for the simple reason, that in experiments, unless the liver is abstracted with lightning-like rapidity, all the glycogen has vanished. My idea of a storage-house has been of a much less transitory or visionary nature. It has always seemed to me that there was no storing-up of glycogen, but rather that the glucose is converted into antecedent products of incomplete oxidation, varying in kind and quantity, but ultimately being oxidized into carbonic acid and water. That occasionally, and perhaps always, glycogen in varying quantities is one of these antecedent products and has been more frequently or is more easily obtained than any of the others, has led to its being looked upon as a stored-up product. Much, however, of the glycogen produced in the system is probably developed from the nitrogenous products, and when oxidation is incomplete it passes as glycogen, or in some other form of antecedent product, to the kidneys, where it is seized by the renal cells and discharged into the uriniferous tubules, giving rise to the condition known as diabetes mellitus.

Second: The liver has its bile-secreting function; that is to say, the hepatic cells produce and discharge into the minute biliary ducts a complex fluid of neutral reaction, which flows on into the larger hepatic ducts, where it is joined by the fluid from the gall-bladder. The function of the gall-bladder is to store up any superfluous production of bile during the interval of digestion. That which accumulates in the gall-bladder contains a varying quantity of alkaline mucus, so that the bile which flows into the duodenum is a thick, tenacious, and somewhat alkaline fluid, while that secreted directly from the hepatic cells is a thinner, more watery, neutral fluid. Having reached the intestinal tract it produces the effects we have already gone over in connection with the functions of the bile as a whole.

Third: The liver is spoken of as having a bile-excreting function—that is, the hepatic cells seem to have the power to attack certain medicinal and other substances which reach the liver through the entero-hepatic circulation, and act upon these poisons in such a way that they are prevented from passing into the general circulation, and are discharged into the minute biliary ducts. From there they pass to the intestines, and, finally, out of the body with the fæces. In this way the system is protected from the poisonous effects which would occur if such substances passed at once and rapidly into the general circulation.

Fourth: The peptone-destroying action of the hepatic cells is somewhat similar to the action just described, in that it destroys the peptone which is now regarded as a ptomaïne and a deadly poison if permitted to reach the general circulation and nerve-cells in an unchanged form. This action differs from the one just described in that the peptone is not excreted from the system with the bile, but is transformed into another, and unquestionably inert, form of albumin. This assertion is sustained by the fact that the portal blood contains a large percentage of peptone, while in the blood of the hepatic vessels we find no peptones, but an increased amount of serum-albumin and globulin. If, however, for any reason this peptone-transforming power is impeded or arrested, and the peptones are permitted to gain access

to the general circulation, symptoms of poisoning are developed in proportion to the amount and rapidity with which the ptomaïnes reach the general system, and also the rapidity with which the excretory organs can expel them from the body. If the quantity discharged into the general system be small and almost as rapidly excreted, the only abnormal symptoms may be a little lassitude, headache, drowsiness, loss of appetite, and high-colored urine. If, on the other hand, they pass into the circulation very rapidly and are eliminated slowly, the symptoms will be more intense; the headache may give place to marked delirium; drowsiness to coma, with nausea and vomiting, constipation or diarrhœa, and scanty and high-colored urine, until, finally, the case terminates in death, with symptoms simulating uræmic or toxæmic poisoning. I believe that all of that host of vague and often ill-defined "bilious" and "neurasthenic" symptoms are best explained by the passage into the general circulation and the incomplete elimination from the body of an almost innumerable number of ptomaïnes and leucomaïnes—products of incomplete nitrogenous oxidation. These poisonous elements circulating in the blood act differently upon various parts of the nervous system and functions of the body, and afford the most rational, comprehensive, and conclusive explanation of an almost innumerable variety of symptoms, sometimes vague and sometimes definite, which are often classed as neurological, but which can be dispersed only by correcting the digestive and hepatic functions. This view is also largely sustained by the known fact that, between serum-albumin as introduced into the body, and its most complete form of oxidation—urea, twenty-eight nitrogenous compounds have already been discovered, and traced into the urine, some of which are deadly poisons. How many there may be yet undiscovered it is hard to imagine, but in time probably many more will be revealed which will make many things that are now but vaguely surmised, actual and thoroughly-demonstrated facts.

Fifth: The liver or hepatic cells are furthur spoken of as having a general ptomaïne- or leucomïane-destroying power besides the peptone-decomposing; that is, they attack all forms of nitrogenous, alkaloidal, and basic substances which may be taken up with the food-stuffs by the entero-hepatic circulation, and convert them, like peptones, into inert substances that can be further utilized for the benefit of the system, or else discharge them with the excreted bile, to be passed out of the system with the fæces. The nitrogenous, basic, and alkaloidal substances developed in the system are probably acted upon in like manner and prepared for excretion. This transformation of ptomaïnes, leucomaïnes, and other poisons by this hepatic action, with the general disturbances in the hepatic functions and in the oxidation processes of the body, together with the general irritation of the increased effete material which is not eliminated from the system as rapidly as it is formed, has always appeared to me to be the true source of our increased bodily heat in disease. All antipyretics, unless they tend to retard these complex and abnormal processes, and bring about in their place normal phenomena, make the condition worse rather than improve the abnormal physiological state. If we can find an antipyretic that will prevent the introduction into, or the development of these poisons within the system, improve the functional chemico-physiological action of the hepatic cells, improve general nutrition, decrease the amount of effete excretory material circulating in the blood, and stimulate the excretory organs to greater activity, then we shall have a true antipyretic. At present, however, no such substance has been found, and it is doubtful if it ever will be. By the judicious administration of various substances we can, in a great measure, modify and overcome this complex problem, and, by so doing, we can very materially reduce the intensity of all infectious diseases and lower their mortality.

Sixth: The hepatic cells are thought by some to have the power to absorb and digest microörganisms—what is known as the phagocytic action. This theory, however, is not so well substantiated as those we have already discussed, but it is quite within the range of possibility that such an action is effected by the hepatic cells. If the microörganisms are not supplied to the liver in too large quantities, they are destroyed by this phagocytic property of the hepatic cells and the system preserved from damage by their presence. If, however, they are carried to the liver in large quantities, this phagocytic function is worn out or overcome, and the system at large succumbs to the influence of the microorganism. The destruction of the germs, however, is more generally attributed to the specific condition or the reaction of the fluids of the body, and not to the digestive action of the protoplasmic masses; at the same time, this protoplasmic destruction of microörganisms, especially in the liver, is in keeping with many of its other chemico-physiological actions, which gives us reason to think that in time we may have more proof of this theory. At any rate, we must go back to the hepatic cells for the chemico vitalizing action upon the blood and through it to all the other fluids of the body.

Seventh: Although this is not included in our table, the liver may be very justly credited with the function of attacking all the food-stuffs and preparing them by the chemico-physiological action of its contained hepatic cells for general distribution throughout the system to sustain the growth, development, and vital actions of the body. Having served their purpose, all the products of tissue-waste come back to the liver as excrementitious substances, there to be acted upon again by the hepatic cells and transformed into antecedent products for final conversion and elimination from the body by the vital action of the various excretory organs, under the form of complete excrementitious substances, such as urea, kreatinine, uric acid, carbonic acid, and water. This action of the hepatic cells may be compared to that of the postal clerks of a large central office, who sort all the mail that comes into the office and start it upon its way, both to the nearest and to the most remote parts of the world. After reaching its destination, it comes back in the form of a reply to the same central postoffice, there to be re-sorted and again sent to its final destination. The mail represents the food-stuffs as they pass through the liver and on to the various parts of the body, as nutriment, and return again to the liver as excrementitious substances. In the liver, as in the post-office, one set of hepatic cells may attack and transform the food-stuffs for distribution throughout the body, while another set may attack the returning excrementi-

tious products and distribute them to their proper organs for elimination. Each individual cell, however, like each individual postal clerk, may be capable of performing both kinds of work, but, for certainty of action and quickness of dispatch, a given kind of work is assigned to a certain set of cells or clerks, yet all are contained within the same walls. The material to be acted upon in each case comes in and goes out through the same channels or doors. Considered in this light, I think we have a far more comprehensive idea of the amount of work, and of the method of its performance, that can be accomplished by the many millions of hepatic cells. We realize at a glance, as it were, the great importance of the liver; we see how a disturbance of its functional activity must disturb the accuracy of action throughout the whole animal economy and give rise to a great variety of symptoms.

Having reviewed the chemico-physiological action of digestion in this complete and continuous manner, I think that you all can accurately appreciate where the major part of the work is accomplished. You now see that the stomach has comparatively little work to do; that very much the larger part of what may be classed as purely digestive and preparatory to absorption is performed in the intestinal canal. Here we find that for the complete accomplishment of this part of the work, and the ready absorption of the liquefied and diffusible products, we are dependent upon the proper quantity and quality of biliary fluid. For this reason I have for a long time been accustomed to look upon this disturbance in the bile-producing function as one of the chief, if not the chief factor, in all forms of digestive difficulties. As we reach the liver, we find much work to be done there, which if imperfectly performed places the entire animal economy in an abnormal condition.

From a careful study of these physiological facts and close clinical observation, I have come to the conclusion that a pure and simple gastric "dyspepsia" is an exceedingly rare occurrence; that in the vast majority of cases the greater part of the trouble originates in the intestines and liver; and that when we do have gastric symptoms they are due to local causes acting upon a poorly-nourished gastric mucous membrane. The truth of these statements is quite perfectly illustrated by our patient to-day.

In my next lecture I will take up the symptoms a little more concisely, together with the treatment of these all-important cases.

ORIGINAL ARTICLES.

HYPERTROPHY OF THE TONSILS.[1]

BY T. HILLIARD WOOD, M.D.,
OF NASHVILLE, TENN.

HYPERTROPHY of the tonsils has occurred at all times with sufficient frequency to claim the serious consideration of surgeons, but the treatment adopted for its relief has been subject to many variations.

The mucous membrane covering the tonsil presents the openings of from twelve to fifteen follicles, the function of which is to secrete a fluid that lubricate the bolus of food in deglutition. These follicles penetrate into the tonsils and terminate in blind extremities. Surrounding the cæcal extremities of the follicles is a quantity of adenoid tissue, and in this adenoid tissue we have, as a rule, the beginning of the tonsillar hypertrophy. The arteries supplying the tonsils, though numerous, are not large, and would not, therefore, if cut, cause troublesome bleeding.

The causes giving rise to hypertrophy of the tonsils may be divided into predisposing and exciting. Of the predisposing influences few are so potent as age. Hypertrophy of the tonsils is essentially a disease of children and young adults. Although rarely congenital, it is frequently observed in the earlier years of life, but more often between the fifth and twentieth years. Not more than one case in ten is older than thirty years, and beyond the fortieth year it is rarely observed. All writers agree that among the predisposing causes a cachectic state, particularly that due to struma, is prominent. Sex also has its influence, for hypertrophy occurs about twice as often in males as in females.

Among the exciting causes may be mentioned acute tonsillitis, pharyngitis, and obstruction of the posterior nares, as by a polypus. Syphilis, either congenital or acquired, may produce chronic inflammation and enlargement of the tonsils. The hypertrophy may arise from diphtheria, scarlatina, measles or smallpox, and difficult dentition, as occurs in cutting a wisdom-tooth, may also cause it.

The enlargement may be seen at once by depressing the tongue and looking into the fauces. The degree of hypertrophy varies in different cases, from the slightest increase to the size of a guinea-hen's egg, when the tonsils may almost meet in the median line. The hypertrophy, though generally affecting both tonsils, is usually greater on one side than on the other. The enlarged tonsil produces the feeling of a foreign body in the throat, and consequently a desire to swallow.

The effect of the enlargement on the features is well illustrated by Mackenzie, who says: "We often predicate the existence of enlarged tonsils as the child, with open mouth, drooping eyelids, dull expression, and thick voice enters the consultation-room." Slight enlargement of the tonsils seems compatible with good health, as the affection is often not noticed by the patient until the overgrowth mechanically interferes with the functions of the pharynx.

The enlargement causes narrowing of the pharynx with difficult inspiration and expiration, the inspiration being the more embarrassed. This obstruction to inspiration necessitates an extra exertion of the diaphragm, and the constant and increased traction of the diaphragm on the thoracic walls

[1] Read before the Tri-State Medical Association, October 15, 1890, held in Chattanooga, Tenn.

causes narrowing and constriction of the chest corresponding to the attachment of the muscle. This "pigeon breast" is best developed when the tonsillar enlargement occurs in young people in whom the osseo-cartilaginous framework of the thorax is soft and yielding.

The enlarged tonsil, by filling up the pharynx and obstructing free nasal respiration, causes the patient to breathe through the mouth, both when awake and during sleep. The current of air through the nose being thus diminished, the nasal secretions are not dried up and blown out as in health, but remain to decompose and set up inveterate nasal catarrh.

Again, the enlarged tonsil is a frequent cause of impaired hearing. According to some, this result is brought about by the organs pressing upon the opening of the Eustachian tube, and so interfering with the ventilation of the middle ear. Another explanation, which is more probably the correct one, is, that the weight and traction of the tonsil produce patulency of the Eustachian tube, the inflammation of the nasal mucous membrane extending through the tube and causing the deafness. The movements of the soft palate and pharynx being interfered with, the voice is altered in tone, becoming thick and guttural. Sleeping with the mouth open, snoring, and awakening to find the mouth and pharynx dry, are frequent symptoms of enlarged tonsils.

The obstruction to deglutition, though less harmful than the obstruction to respiration, interferes with nutrition. Thus the patient, if a child, grows up in bad health caused by a diminished supply of oxygen and food. Perversion of the sense of smell, probably due to the accompanying catarrh, not infrequently occurs with hypertrophied tonsils. Frequent attacks of acute tonsillitis, upon slight exposure to cold, are often observed.

Most cases of enlarged tonsils have their origin in some acute inflammation of the glands previously mentioned. The lymphoid tissue of the tonsil is probably causative in maintaining the hyperæmia, until the stage of hypertrophy is developed. Enlargement of the tonsil is a true hypertrophy, an increase in the amount of each constituent element. The epithelial layer over the tonsil is thickened, and the mucous layer is infiltrated with lymphoid cells and new tissue-elements. But the great increase in the size of the organ is due to the development of connective tissue.

Enlarged tonsils do not directly threaten life, although some isolated cases of death from suffocation are on record. If left to themselves, the new tissue will, in time, undergo contraction, and by the age of thirty years, or soon after, the hypertrophied gland will have returned to a small size. But although all cases tend to spontaneous cure, they produce discomfort, retard the growth and development of the child, and during inflammatory affections of the air-passages become directly dangerous to life. For these reasons they should receive prompt and efficient treatment.

The treatment for the reduction of enlarged tonsils is divided by Mackenzie into local, constitutional, and operative.

Local treatment.—If the enlargement be due to swelling of the mucous membrane, or to engorgement and congestion of the tonsil, the application of astringents may be of service. The most useful local remedies are the subsulphate and perchloride of iron, in a strength of from one to eight parts in water or glycerin, and alum or tannin in powder. But where there is real overgrowth, the remedy, as Mackenzie observes, must be of a destructive character, and escharotics must be used. Among escharotics, "London paste" is useful and should be applied once or twice a week. This will produce a slough, and repeated applications will reduce the gland to a normal size. The treatment with escharotics, while effectual in the end, is quite tedious and painful. When for any reason excision cannot be performed, Donaldson, of Baltimore, incises the tonsil, and inserts into each incision a crystal of chromic acid.

Constitutional measures to effect reduction of the tonsils include such remedies as iodide of potassium, cod-liver oil, and the general tonics, to combat the diathesis upon which the enlargement often depends.

Operative treatment. — Although the writer has used most of the foregoing remedies in many cases, he has not yet derived from any of them decided reduction of the enlarged gland. This reduction can usually be brought about only by the use of some of the operations devised for that purpose. The operation of excision of the tonsil is a very old one, having been clearly described by Celsus during the days of Christ. Since then the popularity of the operation, as a surgical procedure, has been subject to much fluctuation, being at times highly recommended, and at other times condemned. The arguments against it were the difficulty of performance and the danger of hæmorrhage. In 1757, however, Caqué proved that the dread of hæmorrhage had been much overrated, and that the resulting wound readily healed. From that time the operation has grown in favor, and the methods of its performance have been numerous, almost every operator varying the procedure.

Of all the operations, excision by the tonsillotome is most popular, although many surgeons, among them the writer, prefer the bistoury and vulsellum forceps. The operation is rendered painless by

applying to the tonsil a solution of cocaine, and by injecting with a hypodermic syringe a few drops of the same solution into the substance of the gland. The cocaine also checks hæmorrhage. As a rule, general anæsthetics should not be used.

The only danger of tonsillotomy is the very slight one of hæmorrhage, and this has been held by conservative men as sufficient to condemn the operation. Let us examine into the matter of hæmorrhage after tonsillotomy. Sajous says: "Profuse hæmorrhage occurs in perhaps one out of every five hundred operations, while an alarming flow does not occur in one out of a thousand." Mackenzie, during a long experience, can recall only one case in which hæmorrhage seemed to endanger life. The records in the Surgeon-General's Office at Washington, D. C., for the past twenty-five years, show only two deaths from hæmorrhage after tonsillotomy, and in one of these, a child eight years old, the cause was an anomalous course of the internal carotid. In the other case the patient was twenty-five years of age.

Statistics show, however, that free bleeding occurs in about one per cent. of cases, and in one thousand operations collected by J. Solis-Cohen there were four deaths. But while the danger from hæmorrhage in children, in whom the tonsillar tissue is loose, and therefore readily collapses and arrests bleeding, is almost *nil*, yet in adults the fibroid elements, now in excess, and which relatively increase as age advances, form a tissue less favorable for the retraction and closure of the cut vessel than the spongy mass of a young tonsil largely composed of lymphoid tissue. (Wright.)

This explains why the cases of alarming hæmorrhage occur almost entirely in adults. Many operators of large experience have never lost a patient from hæmorrhage, and have only seldom seen it become severe. There are no large vessels supplying the tonsil, and experience proves that the bleeding after tonsillotomy ceases spontaneously, or is easily controlled by the application of nitrate of silver, by iced-water gargles, or by cold cloths applied to the neck. Should the bleeding be severe we may use Mackenzie's gallo-tannic acid paste, perchloride of iron, torsion, pressure directly applied, ligature of the stump, or the actual cautery. Should these fail the common carotid may be ligated —recovery took place in three recorded cases in which this was done. In two of the six fatal cases referred to above, the common carotid was not ligated. So that the alarming danger of hæmorrhage resolves itself, according to the records of the past twenty-five years, into two fatal cases, and there is no evidence to show that the previously-mentioned means to arrest bleeding were employed in these two cases. Still, bearing in mind the fact that all the fatal cases have not been reported, it is evident that the entire number, after all, is not so small.

To diminish to a minimum the danger from hæmorrhage, we have the comparatively bloodless operation by the cold snare, operations by ignipuncture, and by the galvano-cautery amygdalotome. Of these the galvano-cautery amygdalotome seems preferable, and is highly recommended by Wright, of Brooklyn. Ignipuncture is tedious, requires repeated applications, and is attended by considerable pain. Moreover, it cannot be employed in the cases of refractory children.

HOW A GENERAL PRACTITIONER MAY TREAT CHRONIC ATROPHIC RHINITIS.[1]

BY HANAU W. LOEB, A.M., M.D.,
LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE MARION-SIMS COLLEGE OF MEDICINE; ATTENDING SURGEON TO THE NOSE AND THROAT DEPARTMENT OF THE GRAND AVENUE FREE DISPENSARY, ST. LOUIS.

FROM the time when the Chinese Emperor, Hoang-ty, 4500 years ago, first described specific ozœna, until the present day, the treatment of chronic atrophic rhinitis has been, more or less, the bugbear of the general practitioner of medicine. The disease now lacks many of its mystifying elements, but even in this enlightened day it remains a stumbling-block in the practice of many physicians.

Notwithstanding the great amount of literature which has resulted from the painstaking study of this disease, the vast majority of doctors are indifferent, some perhaps ignorant, as to its proper treatment. Some do not believe that an iota of benefit can result from treatment of any kind; others declare that they have no desire to treat it; while still others, by temporizing, hold their patients day in and day out, in the vain hope that some kindly providence may relieve doctor or patient. Amid all this array of indifference, disinclination, and lack of knowledge or of its application, is it strange that the poor sufferer should read, with a shudder, the advertisements which describe his symptoms so exactly, and which alarm him by unnecessary warnings of dangers which never occur? Is it to be wondered at that his mind becomes filled with visions of consumption—visions which, by reason of their indistinctness, magnify the evils thus portrayed? Is it remarkable that he should swallow with avidity such unwholesome morsels as this? "The microbe of catarrh, in your sleep, crawls down your throat, and, coming in contact with your lungs, produces consumption." Is there occasion for further wonder that the poor, bewildered mortal, whose fears have now changed his nose into a mountain of woe, should seek his family

[1] Read before the Medical Society of the Missouri Valley, Kansas City, Mo., December 18, 1890.

physician, and receiving the unsatisfactory advice—which in many cases he will get—is it strange (say I) that he should place himself in the hands of a quack? I think not. From a popular standpoint, at any rate, the charlatan who loudly boasts of his cures, and who points out the evils that may result, knows far more than the dilly-dallying doctor. Here lies the trouble—doctors imagine the nose is beyond their ken—too far removed for their comprehension; in fact, many do not hesitate to say so, though these same doctors would never admit a lack of knowledge in the treatment of a cervicitis or an endometritis, and yet the organs concerned in these diseases are far more difficult to examine than the nose.

Thoughts such as these are calculated to make a specialist ponder, and to seek for some plan of benefit. That some good may come from a tacit and clear statement of the treatment of this disease, I am sure, and that the general practitioner will, by the application of a few general rules, be able to benefit almost all of these cases, I am certain. I have seen this very thing exemplified in my own students in the Marion-Sims College of Medicine, to whom I have assigned cases for treatment in the Clinic, with highly-satisfactory results. If students are thus capable of treating nasal catarrh, I feel certain that the great body of conscientious practitioners of medicine can do far better. Many means have been devised and many remedies have been suggested for the treatment of this very refractory disease, but as its theoretical consideration forms no part of the subject of this paper, they will not be considered. Therefore the radical treatment of the disease, requiring, as it does, an extensive knowledge and technique, will not receive attention. That the disease is ever entirely cured is still a controvertible question. Reports have been made of cures by cauterization with chromic acid and the galvano-cautery, and by galvanism of the nasal mucous membrane.

From the nature of the disease, and the abnormal secretions which it causes, one can easily understand that two features of treatment are indicated, viz: cleanliness and stimulation—cleanliness so that there can be no irritation from the presence of scabs, and for the thorough application of medicines; and stimulation to counteract the passive inflammation, and to cause the mucous membrane to approximate more nearly the normal by filling it with wholesome blood.

Cleanliness does not mean promiscuous douching or spraying of the nose. The greatest care must be taken to remove every scab and particle of abnormal discharge. This can be done by the general practitioner readily enough, and his armamentarium need not be very extensive. A lamp—a student's lamp being preferable—a head-mirror, a nose speculum, a small cotton applicator (a knitting-needle with one end roughened will answer) constituting an equipment not elegant, but sufficient. The cost, exclusive of the lamp, is little enough, being less than $4. Cotton, absorbent or borated, should be on hand, as well as plenty of Dobell's solution, or the following modification, which I like better:

℞.—Sodii bicarbonatis } . . āā ʒij.
Sodii biboratis }
Listerine or "katharmon" . . ℥ss.
Aquæ q. s. ad. . . . . ℥viij.—M.
Sig.—Nosewash.

To the list I should perhaps add some sort of atomizer or post-nasal syringe, costing in either case not more than $1.25. However, one could get along without either of these. The nose should first be sprayed out with the solution the formula of which I have just given (better warmed), or by means of the post-nasal syringe the cavities can be washed out from behind. Understand, however, even this does not constitute true cleansing of the nose, for after this has been done the work really begins. The light being reflected into the nose, held open by means of a speculum (Knight's modification of Duplay's preferred), the probe, to which a pledget of cotton is attached, is made to dislodge and remove each scab or portion of discharge which is presented to the view. Anyone can do this, for anyone can see the scabs and can with ease remove what he sees. This accomplished the nose is clean, and the first essential part of treatment has been applied.

For the stimulative plan of treatment various drugs have been recommended, out of which I select menthol, thymol, and eucalyptol as having been most efficacious in my hands. I have used menthol more frequently than any of these agents, and have been so well pleased with its action that I should be unwilling to exchange it for any other remedy. The following is the customary formula:

℞.—Menthol . . . . . gr x.
Liquid albolene . . . . ƒ℥j.—M.
Sig.—Spray for the nose.

The amount of menthol may be increased to twenty grains or even one drachm to the ounce. This, or thymol, ten grains to one ounce of liquid albolene, or eucalyptol, ten drops to one ounce of liquid albolene, should be well sprayed into the nose, first directing the patient to breathe through his mouth, thereby shutting off the oro-pharynx and causing the spray to pass out of the other nostril. The first sensation is that of warmth, and no little itching is frequently occasioned; but this is soon succeeded by a feeling of coolness and comfort in the nose which is gratifying to the patient. While

the menthol, thymol, and eucalyptol have a stimulative effect, the liquid albolene is not void of benefit. It takes the place of vaseline, but possesses nothing of the almost nasty characters of the latter. By means of the spray, the oily albolene is thrown over a large portion of the mucous membrane, and by covering it with an oily film, aids not a little in its improvement. This cleansing treatment of the nose should be resorted to every day, if possible, for some little time; later, the intervals may be lengthened. It is useless to attempt to produce any permanent or even transitory improvement, by treating the nose twice a week or less; three times a week is seldom sufficient at the outset.

Nor is this all there is in the treatment. The patient should be directed to clean his nose three or four times daily, by snuffing up Dobell's solution or the modification which I have given, and thereafter using a spray of menthol, thymol, or eucalyptol and albolene. A special form of atomizer must be used, because all atomizers do not act with oily solutions. Each patient must provide himself with one, and use it three or four times daily. The Codman & Shurtleff No. 356, or the Brooklyn Throat Hospital Atomizer, will answer. The latter is better for the doctor, in that having three nozzles it may be used for the nose, pharynx, or larynx.

Of late I have been using a new atomizer, lately designed and manufactured by the A. M. Leslie Surgical Instrument Company, of St. Louis—the Acme Vaseline Atomizer; in fact, I now prefer it to any other kind. It has the advantage of simplicity and cleanliness. Though intended as a vaseline atomizer, it can be used with the greatest satisfaction for the spraying of liquid albolene. I would again urge that the atomizer be used systematically, thoroughly, and regularly. It is surprising how much better the patient will become under this treatment; the excessive scabby discharge ceases, the odor disappears, the hawking diminishes, and the patient's mind turns to other thoughts than an untimely death from the fancied change of catarrh into consumptton.

It is well to state one danger which may occur not only from this form of treatment, but in any case where douching of water is used: I refer, of course, to otitis media, catarrhal or suppurative. Where there is the slightest tendency to this disease, one must be guarded and must avoid the douche, and sometimes the spray. In such cases, the only recourse is to remove the scabs as well as possible by means of a probe and pledget of cotton.

Very naturally there are other plans of treatment which are not to be despised. I desire to make no reflection whatever upon any other method. This I do say, however: the method which I have detailed is one which must commend itself to everyone. It is simple in its application, and sufficiently easy in detail as to be within the range of every practitioner of medicine.

3148 LOCUST STREET.

A CASE OF ACTINOMYCOSIS.[1]

BY A. J. OCHSNER, M.D., B.S., F.R.M.S.,
ATTENDING SURGEON TO THE AUGUSTANA HOSPITAL, CHICAGO.

THIRTEEN years ago Bollinger showed that the disease in cattle know as "lumpy jaw" is due to a parasite, and a year later Israel found the same parasite in the discharge from an abscess connected with the pleural cavity in a woman. The parasites were named actinomyces, and the disease actinomycosis.

The disease is very common in the cow, less common in the pig and horse, and, according to recent observations, not very rare in man. It most commonly attacks the tongue ("woody tongue" of cows) and the lower jaw, but has been found in every organ, reaching the different parts of the body, either by continuous growth or by being carried through the blood- or lymph-channels from the original focus.

The parasite is a fungus, not yet permanently classified, composed of radiating filaments, somewhat club-shaped at the ends, but frequently split into a number of smaller parts. Under the microscope it can be recognized with a power of 250 diameters, but it requires an immersion lens of from four to six times this power to make apparent its finer subdivisions. One can, however, recognize collections of these fungi with the naked eye. They form small, pale-yellow granules, reminding one of mustard-seeds which have been immersed in liquid.

When the location of the infection favors the formation of a tumor of considerable size, the tissues composing the growth are also characteristic to the naked eye. They resemble loose, flabby, granulation-tissue interspersed with the characteristic yellow granules. Each of these granules contains a number of microscopic spherules, and each of these is one of the fungi. The fungi can be readily demonstrated by immersing one of the granules in a ten-per-cent. solution of potassium hydrate in water, and placing it under the microscope. The pressure of the cover-glass crushes the spherules and makes them somewhat irregular. The parasite can be stained most conveniently by Gram's method, either on the glass slide or in sections, but for diagnostic purposes staining is not necessary.

The manner in which the parasite enters the body is often obscure. It may enter through an external wound, through a hollow tooth or an abra-

[1] Read before the Illinois Microscopical Society.

sion in the mouth, through an abraded surface in some part of the alimentary canal, or by inhalation through some part of the respiratory tract. In many cases infection might easily have been prevented if it were generally known that "lumpy jaw" in cattle can be transmitted both directly and indirectly to man, and that the disease in man is quite as fatal as in animals. Very frequently the manner of infection can be directly traced. A farmer or drover will, for instance, use the jack-knife that he carries in his pocket, for the purpose of opening a tumor in a case of "lumpy jaw," and later will use the same knife for cutting his own food. Again, such persons handle these animals and then eat without washing their hands, or they drink out of pails or from pumps which have come in contact with diseased animals, or use spears of infected hay or straw as tooth-picks.

It is almost certain that the parasite lives and thrives on the surface of several plants, and that it is frequently introduced together with parts of these plants or by coming in contact with some abraded surface, and that in animals infection very frequently takes place from wounds of the gums, which become filled with these parasites while the animal eats grass, hay, straw, or grain on which the parasite has developed. So much for our present knowledge of this disease.

The case that I have under observation at present is a gentleman fifty-three years old, a farmer by occupation, healthy until eight months ago, when he began to suffer from severe continuous pain in the region of the left antrum of Highmore. He had four decayed teeth removed from the left upper jaw but was not relieved. Soon after this an abscess formed and pointed on the cheek at a position opposite to and a little above and behind the canine fossa. This was opened by his physician, and subsequently twice opened spontaneously before he was referred to me at the Augustana Hospital, August, 1890. When I first saw him, the skin surrounding the sinus was thickened and infiltrated, and a drop of pus squeezed from the sinus contained the characteristic pale-yellow granules which were proved to contain actinomyces.

The treatment consisted in removing all of the soft tissues which were involved, in chiselling away the outer surface of the antrum, thoroughly curetting the cavity, swabbing it out with ninety-five-per-cent. solution of carbolic acid and then packing it with iodoform-gauze. The wound healed normally from the bottom by granulations, and the patient did well until October, when an œdematous mass appeared above his left ear. I opened this and again evacuated half an ounce of pus and granulation-tissue containing the same characteristic granules in which were the parasites. This cavity was also packed with iodoform-gauze and is healing by granulation. The patient is now doing well, and unless the parasite has advanced to some other point, which cannot as yet be determined, he will undoubtedly permanently recover. Infection in this case probably took place through the patient's decayed teeth. From October, 1889, to February, 1890, he had handled and treated a horse supposed to be suffering from "lumpy jaw," and not knowing the dangers of infection had been rather careless.

Four years ago I reported a case of actinomycosis of the lungs.[1] The patient was treated with arsenic and sent to New Mexico, where, I am told, "lumpy jaw" does not occur among cattle. He lived four years, and died last June from actinomycosis of the lungs, judging from the statement of friends. No autopsy was made.

When I first treated this patient I made a number of experiments on animals, inoculating rabbits under the skin of the ear and in different parts of the body, but with negative results. The material used for inoculation consisted of the granules found in the sputum of the patient. The last experiment that I made consisted of inoculating a rat between the teeth. About two weeks later the animal disappeared, but in two months the mate of this rat died from actinomycosis of the shoulder and neck. Not having inoculated the mate, and having lost the original rat, I never reported the experiments, but, of course, it is probable that the mate was infected with actinomycosis by the inoculated rat. The rat was kept in a large room where it could easily get under some boards; it probably became ill, and hiding somewhere, died from the disease.

CONSERVATIVE SURGERY IN INJURIES OF THE FOOT.[2]

By J. T. WILSON, M.D.,
OF SHERMAN, TEXAS.

Even with the modern methods of surgery there are many feet sacrificed to a want of patience and proper management of the injuries that may have been received. It is, doubtless, true that injuries of the foot, as we have been taught, are more serious than those of the hand, because the foot is larger, and at a greater distance from the centre of circulation, and hence has less power to repair mischief, and is much more susceptible to suppuration and gangrene, yet it is very amenable to treatment. It should ever be the surgeon's earnest desire and aim to save the foot, and, if possible, in a useful shape. With the knowledge of the subject, and the resources we possess at the present day, the successful treatment of injuries of this part is more certain and satisfactory than formerly. I have seen several cases of foot injuries in which the member was sacrificed to a want of patience and good judgment—cases that in all probability would, with careful attention, have

[1] Medical Journal and Examiner, December, 1886.

[2] Read by title before the Southern Surgical and Gynecological Association, November 12, 1890.

been restored to their former usefulness. Some surgeons prefer amputation and treatment of the stump to what may seem to promise prolonged attendance upon a slowly-healing wound; but the loss of even a portion of the foot, or of several of the toes, is so serious that we should not permit our personal preferences to influence our judgment against conservative treatment when there is a possibility of the part being saved.

CASE I.—Some years ago a man came under my observation about twenty-four hours after having had his foot caught between two heavy logs. There was some excoriation, but the true skin was not broken, all of the metatarsal bones, except the fifth, and one of the phalanges of the second toe, were fractured, the internal cuneiform being displaced. The foot was greatly swollen, bruised, discolored, and painful, and the attending surgeon was of the opinion that amputation by Chopart's operation was the best treatment. But after further careful examination and consultation, the circulation appearing not to be seriously interfered with, it was decided to wait for a day or two. Under the influence of chloroform the displaced bone was pushed into position without much difficulty. The foot was immersed in hot water, carefully bathed, gently rubbed with a soft cloth and the hand, and then was enveloped in a layer of cotton-batting held in place by a well adjusted bandage and splint. The pain was much relieved, and the patient passed a comfortable night. The dressing was changed once daily after the second day, the foot being bathed and rubbed with sorbefacients, and the bandage tightened a little after each dressing. It was practicable by much care to keep the fractured ends of the bones in apposition, and thereby good union was secured. The general health of the patient was excellent. He recovered without deformity, and the foot was restored to its former usefulness.

CASE II.—Another case was that of a boy, whose foot had been caught under one of the wheels of a heavy truck, the uneven surface and the soft ground doubtless protecting the member from a much greater injury than it actually received. He was taken into the office of a physician near by, who called a consultant, and after an examination under chloroform it was decided that amputation was the only remedy and I was requested to do the operation. I found upon examination a lacerated wound, about four inches long, upon the outer dorsal surface, and involving the heel; there was crepitation over the dorsal surface, but it was the crepitus of air which had penetrated the cellular tissue. I could not detect any fracture. It was then determined to envelop the injured part in an antiseptic dressing. It is needless to say that this boy's foot was completely restored to usefulness.

CASE III.—In a gunshot wound the ball, from a 0.45 calibre Colt's revolver, penetrated the instep and lodged in the scaphoid bone. Fifteen hours after the accident the case was examined, but the ball could not be found. The foot was then put at rest and cold-water dressings adopted. In five or six days the man became restless, and bundling up his foot began his occupation, that of a laborer, and though it gave him considerable pain, he would not remain quiet, or give the wound much attention. Soon after this, inflammation began in the bone, followed by suppuration and pain for many months. The bones became enlarged and tender and the tissues infiltrated, and the patient's general health failed. He was anxious to have an amputation performed above the ankle. However, I removed the diseased tissue and bone, irrigated the wound thoroughly with a solution of carbolic acid, made counter-openings in the sole of the foot and inserted drainage-tubes. The parts were kept perfectly clean, and at rest in as comfortable position as possible. Tonics and good food were administered, and the patient began to improve at once, and recovered with a useful foot.

CASE IV.—A man, while chopping wood, wounded his right foot just above the metatarso-phalangeal articulation, and profuse hæmorrhage followed, but was controlled. An aneurism of the lower portion of the dorsalis pedis artery formed, and in the following five months he had two serious hæmorrhages, which were very difficult to control. Inflammation and suppuration set in, involving the first and second matatarsal bones. It was thought by the physicians who saw him that amputation of the foot would be necessary, and he was in constant dread of hæmorrhage. I was requested to see him, and after consultation we decided to ligate the dorsalis pedis artery and remove the dead bone. After the ligation the carious portion of the first metatarsal was scraped away and the phalangeal extremity of the second metatarsal resected. Recovery was rapid. This man having valvular disease of the heart, and being somewhat prostrated from previous loss of blood, he narrowly escaped death from chloroform-narcosis.

A majority of surgeons have methods of their own for surgical operations and dressings. A new method is exceedingly rare, but many surgeons think that their own mode of doing an operation or of applying a dressing has advantages over others, and it is well that this is so, because it gives the surgeon more self-confidence and self-reliance, and enables him to do greater service to his patients. Then, too, a different application of the same principle may effect different and better results. With antiseptic methods suppuration of the foot of a healthy person can almost invariably be prevented, even though the tissues be much bruised and lacerated. By a careful attention to the injured part and the general system, by absolute rest and a judicious dressing, the bruised tissues will soon regain their normal condition if the bloodvessels be not destroyed and the circulation not entirely cut off.

An njury of the foot of whatever nature irritates the nerves, tendons, and muscles, and induces contraction, which is painful, interferes in some measure

with the circulation of the blood and retards the healing of the wound; it is, therefore, necessary in such conditions that complete rest be given, and this can be accomplished by bandages, splints, slings, and props. Position is important, because by this means comfort may be secured and the displaced parts adapted to their natural position, which is the more favorable one for repair. The circulation can be regulated by gentle, efficient massage and by changing the position from time to time. It is important to restore the circulation as soon as possible after the injury has been received, and this can be accomplished by keeping up the temperature of the part. Usually the foot placed on a level with the body, or a little higher, is the most favorable position, but it can be changed to a higher or lower one, sometimes with great benefit; when the circulation is feeble a dependent position at short intervals and for varying periods will act advantageously.

The same dressing will not answer in every case. In some injuries splints are necessary, or plaster or starch bandages; in others a simple roller or a sling is better. The dressings of cold water will do more good in some and warm or hot water in others. In some cases a liniment will serve the best purpose, in others an ointment. In many open wounds, especially if the surface is suppurating, an antiseptic unirritating powder, such as boric acid, iodoform, iodol, bismuth, oxide of zinc, powdered hydrastis, etc., will be of the greatest service. I have had no experience with the new antiseptic *aristol*.

The general system should be carefully attended to; it may be in a bad condition when the wound is received, or from confinement it may become so soon after, and this will be an impediment in the progress of repair. Attention to the secretions, to digestion and assimilation, to the functions of the liver—especially in a southern climate—skin and other organs plays an important part in the management of these cases.

In contused and lacerated wounds the best results are obtained by keeping the foot at absolute rest in a comfortable position during the first part of the treatment, by cleanliness and by soothing applications. Punctured wounds of the plantar surface are generally regarded as more dangerous than similar wounds elsewhere; complications are more common, tetanus is more frequent, and there is more trouble in causing the wound to heal. Removal of foreign substances, antisepsis, and free drainage will accomplish satisfactory results in nearly all cases.

In gunshot wounds the parts are generally much lacerated and bruised. We should persevere in our efforts to clean the wound of every particle of foreign substance, clip off all ragged edges, and convert it as nearly as practicable into an incised wound. The ligatures and sutures should be thoroughly antiseptic. The fractured ends of bones and the soft parts should be nicely coaptated and carefully maintained in position for the first few days in as near absolute rest as possible. Contusions of the bones are frequently far more serious than those of the soft parts; inflammation is more liable to be set up and to be followed by suppuration, caries, and necrosis. In bad sprains of the foot immersion in water as hot as can be borne soon after the occurrence of the injury, boiling water being added until the temperature is raised to the highest degree of tolerance, will do more than anything else to relieve the acute suffering and lessen the swelling. This should be followed by a gentle shampooing, while the foot is elevated above the level of the body until the surface is quite dry. A plaster bandage should be applied in such a way that the circulation will not be interfered with, and the foot placed in a comfortable position and retained for a few days at complete rest. Then the bandage should be removed, the shampooing again instituted, passive motion carefully and gently begun and repeated at intervals. This treatment requires good judgment and patience, but is very satisfactory, and, I believe, in those rare cases in which the safety of the foot is endangered, will often prevent serious consequences. I am of the opinion that a wounded foot should receive antiseptic treatment, whether the skin is broken or not.

I have thought that my results were much better in cases in which I thoroughly washed the whole foot in hot antiseptic solutions. The somewhat uncertain state of the surgical mind in regard to the antiseptic treatment of wounds and in the choice of an antiseptic, should not cause us to neglect these precautions. That antiseptic surgery has marked perhaps the greatest advance known to our art, the bold operations of to-day, the explorations into every cavity of the body conspicuously testify; that under its use there is a more rapid and ready union of wounds, less suppuration, and fewer cases of septic poisoning than under the old *regime*, is patent to all. In cases in which it is impossible to prevent suppuration, drainage-tubes may be used with benefit so long as they seem to be actually required, and removed as soon as they cause irritation. Some cases too, with profuse suppuration, require counter-openings in a different part of the foot to insure perfect drainage.

If a plaster bandage is too heavy, a starch or silicate of sodium bandage makes an excellent substitute. In a highly-inflamed and swollen foot ice properly applied is capable of doing much good, but should not be allowed to remain long. While poultices in the same conditions can be applied with advantage, they will, on the other hand, do harm if

not removed before they cause maceration and irritation of the skin.

Hæmorrhage should be controlled as soon as possible and clots removed, the parts cleansed of all foreign bodies, such as earth, sand, clothing, detached pieces of bone, and badly-bruised and lacerated tissues. Extreme tension is best relieved by incisions, the wounds irrigated with an antiseptic solution. Catgut is, I think, the best suture for the foot, but if not at hand, sterilized silk or flax thread may be used. I deem it an important point to have all thread used for ligatures and sutures previously well boiled and immersed in a strong solution of carbolic acid.

In bringing the edges of wounds together the sutures are frequently drawn too tight and when swelling occurs they are liable to cut their way through the inflamed tissues, and interfere with union. I have obtained the best results by changing the dressings as infrequently as is compatible with an aseptic condition of the wound.

Massage is important in the treatment of extensive wounds of the foot; it stimulates the blood-vessels, muscles, and functions of the limb. If the skin is not broken, and tension not extreme, massage will assist in the absorption of fluids.

In cases in which an operation is necessary, if there be shock, by the free use of antiseptic dressings and controlling hæmorrhage if present, the operation may be deferred until shock has been recovered from.

Immediate union should be secured, if possible, in all wounds of the foot. When, for any reason, the wound cannot be closed, it may be successfully treated by the open method, and antiseptics have rendered this mode very satisfactory in many cases. If bloodvessels and nerves are not sufficiently destroyed to cause the early death of the part, amputation should not be hurriedly performed, even though it seems improbable that the foot can be saved. While there is living tissue it should be given the chance for repair.

Resection of the bones of the foot can frequently be performed with gratifying success. Dr. Schuchardt,[1] of the German Army, in discussing excision of joints in gunshot wounds, states that "the formation of new bone is less copious under the antiseptic *regime* than formerly, which is a decided advantage, but one which is amply compensated for by the fact that the antiseptic *regime* admits of more conservative treatment."

Tendons and nerves can often be sutured, and frequently unite; and ulcers can be made to heal by scraping away all necrosed and unhealthy tissue, and by rest and antiseptic dressings. Even gangrene following extensive burns and frost-bites will often terminate surprisingly well and without the loss of the entire foot if carefully managed. The most serious consequences sometimes result from apparently insignificant wounds, and with this fact in view it behooves us never to overlook an injury brought to our notice, no matter how trivial it may appear.

The secret of success in the treatment of foot-wounds lies in vigilance, patience, and persistence, and in giving the strictest attention to all details; the disregard of which is the cause of many failures.

The temptation to make a brilliant operation through some joints of the foot may seem too great to resist; but we should not permit such a temptation to warp our judgment nor lead us to sacrifice the part. Such an operation may present an appearance of beauty and seem scientific in the highest degree to the unprofessional observer, and will probably add to the surgeon's reputation among the laity, but the consciousness of having sacrificed a part of the foot to the desire for *éclat* would, as Professor Gross used to say, "bring the blush of shame to our cheeks," whenever we should meet our unfortunate victim face to face.

THE GENERAL AND LOCAL TREATMENT OF GANGRENOUS WOUNDS AND DISEASES.[1]

BY BEDFORD BROWN, M.D.,
OF ALEXANDRIA, VA.

THE surgical procedures in gangrenous affections, the proper stage for operation, and the propriety and necessity of operations in certain conditions, are questions already so well settled that nothing can at present be added to our knowledge of the subjects. Therefore, it is not proposed in this paper to allude to these questions, but to discuss the various methods of treatment, both of a local and general character, found by the writer to be the most efficient for the prevention and arrest of gangrene. We know that traumatic gangrene is more amenable to treatment than is the idopathic form, from the fact that the former is of a more transient nature, while the latter is usually more dependent on certain fixed organic changes, such as the arterial degeneration of old age, thrombosis of large arteries, embolism, or certain blood-changes.

Previously to the late war I determined to institute a series of experiments in every case of gangrenous wound or disease coming under my observation, on the capacity, or rather capability of therapeutic agents, and of various local and general methods of treatment to prevent or arrest the process of these affections. As gangrene is not actually a disease, but rather the sequence of disease, the

[1] Read before the Southern Surgical and Gynecological Association, November 11, 189.

direction of the treatment must of necessity be addressed to such diseases or conditions as may give rise to it, as well as to the peculiar sequence itself. It is proper here to consider briefly the various forms of gangrene in their relation to treatment. Probably the largest number of cases of gangrene are of the traumatic variety, and arise from lacerated, contused, crushed, or poisoned wounds, in which the vasomotor nerves of the part are paralyzed by the local shock, or structural damage occurs, from which blood-stasis results, and the nutrition of the parts is suspended. Here something else is needed besides antiseptics and disinfectants. Potent stimuli to the paralyzed vasomotor nerves and to vital action are also necessary. If vasomotor action can be aroused in these cases, nutrition of the injured part sustained, and disinfection accomplished, then the progress of the gangrene may be arrested.

The most important varieties of the idiopathic affection are the dry and moist forms arising from embolism or from thrombosis of a main artery. In the treatment of this class of cases the question confronts us in the beginning: Are there any means or methods that are actually capable of arresting its progress, and saving life, or avoiding the necessity of amputation? When the main artery of a part is obstructed from thrombosis, either transiently or permanently, and the distal extremity is dying from innutrition, can any method be devised by which a collateral circulation can be established to supply the place of the original circulation, reëstablish the nutrition of the parts, and arrest the process of gangrene? I feel sure that this has been accomplished, and in the course of my paper I will cite an example in which dry gangrene of the lower extremity, arising from occlusion of the popliteal artery, with absence of all pulsation in the posterior and anterior tibial arteries, and in the peroneal artery, above the gangrene, nevertheless had a collateral circulation sufficient to arrest the gangrene and save the limb so that the extensive excavation left from sloughing healed.

Hospital gangrene is probably due to a combination of influences, namely, an infectious poison acting on a wound in a constitution impaired by the various depressing influences of army-life and the hardships of war. During the recent war, in the field-hospitals under my charge, I found that separation of the wounded at great distances; their removal from house-tents, and the substitution of tent-flies under trees in high, unused localities, where fresh breezes could have fair sweep; the frequent and systematic changing of their location; the burning of all débris on the old localities; the methodical enforcement of cleanliness; and the administration of nourishing food, with the application of hot boiled water, and a saturated solution of the sulphate of zinc and dilute sulphuric acid to the gangrenous wounds, gave better results than any other method. Most of the valuable antiseptic agents now in common use were then unknown, or were not used as antiseptics. This is true of that most wonderful antiseptic, *bromine*, and while I have had no personal experience with this remedy in hospital gangrene, I have sufficiently observed its powers in other forms of gangrenous affections to convince me that it is one of the most potent agents for the treatment of this class of diseases. When diluted it possesses antiseptic and disinfectant properties, without caustic or destructive action. Here I wish to note the great differences in the method of treating gangrenous affections in ancient and in modern times. In retracing the history of the treatment of gangrenous affections the further we go back the more common do we find the use of destructive caustics, until we reach the traditional application of the actual cautery in its various forms. A single fact strikes our attention in this history, and impresses itself indelibly on our minds, and that fact is the utter failure of these violent measures to save human limb or life. The silent, painless, potent operation of the modern antiseptic and disinfectant, as they destroy germ-life and convert the most deadly animal poisons into innocuous and harmless matter, is in marked contrast with the horrors of the old caustic system. In our treatment of gangrenous diseases let us abandon the crude, barbarous systems of the past, and discard all caustic agents which have no power to correct sepsis, or infection, but which only destroy the living tissues.

In the study and practical treatment of these affections, we find that antiseptic and disinfectant action is not all that is necessary. We may destroy the primary germ and the poisonous ptomaïne, and still not be able to restore healthy vital action in the parts, or prevent the progress of necrosis. It was this hope of restoring vital action which led the ancients to use caustics and cauteries as local stimulants. I believe that we possess active stimulants of vital action which are devoid of all caustic or destructive power, and that there are certain agents which have a specific power of this nature. The agents of this character which I have relied on most frequently, and for the greatest length of time, are a concentrated solution of the sulphate of zinc and dilute sulphuric acid after the following formula:

R.—Sulphate of zinc . . .	1 ounce.
Dilute sulphuric acid . .	4 drachms.
Water	1 pint.—M.

This mixture is one of the most potent stimulants of vital action in gangrenous tissues, or rather in the

contiguous tissues, and is one of the most effectual means of arousing vasomotor action in the capillary vessels when vitality is impaired but not lost, of which I have any knowledge. At the same time it causes the gangrenous tissue to shrink and separate from the sound parts, often with unexpected ease and rapidity. I have experimented with this combination in a large number of cases of sloughing wounds and tissues, some limited, others extensive, in the past thirty-two years, with favorable results in the great majority of cases. During the late war I found it invaluable. In gangrenous or sloughing wounds, in which the process of mortification is rapidly progressing, with utter loss of sensibility and entire vasomotor paresis, and with the tissues breaking down extensively, without any tendency to establish a line of separation, it has often given me excellent results. It is exceedingly cleanly, and when acting favorably changes the offensive, fœtid, filthy parts rapidly and effectually. The action in many cases in hastening and facilitating the separation of the sloughs has been most satisfactory, leaving in the place of the sloughs a healthy basis for granulation. Under this influence I have known large areas of sloughing matter to be thrown off in forty-eight hours, and a healthy base to be established. I have usually applied the solution every three hours by means of cotton-wool. If the sloughs are dense and impenetrable the solution is also injected into them. When healthy tissue is found after the separation of the sloughs, the further application of this solution is no longer admissible, as its contact with the parts gives rise to intense pain. I know of no local stimulant that acts more promptly than this in developing renewed sensibility and vital action in tissues which are on the verge of gangrene and breaking down from necrosis. In small sloughing wounds I have found its action exceedingly prompt in removing the sloughs and leaving a healthy surface for granulation.

Another disinfectant, antiseptic, and potent stimulant of vital action in gangrenous diseases is bromine in solution. I usually employ as a local application two drachms of bromine in one pint of water. In this strength it may be freely applied to sloughing parts, and when the slough is impenetrable, injected into the gangrenous tissue. In certain cases in which gangrene was arrested by the use of bromine and in which cicatrization was completed after the suspension of the remedy, inflammation with a tendency to sloughing again commenced. A return to the bromine treatment invariably corrected the infection, arrested the inflammation, and changed the vital action in the parts with the result that healing again took place.

I cannot but regard a remedy combining these varied qualities as of infinite value. I repeat the assertion that of all local agents which aid in stimulating vital action in gangrenous structures, and in hastening the separation of the dead from the living tissues, the solution of bromine, dilute sulphuric acid, and concentrated solution of sulphate of zinc, in my experience, surpass all others. I desire to dwell especially upon the antiseptic and disinfectant properties of bromine, not simply as regards its local action, but also its power, when liberally applied, to prevent that form of septicæmia which arises from sloughing affections or wounds. If future experience should confirm this view, we have made, in the past few years, a great advance in the treatment of gangrene and its consequences. During the recent war I saw cases of septicæmia or pyæmia arising from wounds not more than two inches in diameter. I then treated all cases of this character under my charge by the local application of the concentrated solution of sulphate of zinc and dilute sulphuric acid, and with a fair degree of success. But the alternate application of these preparations and the solution of bromine as local means, leaves nothing to be desired.

I here wish to allude to my experience with the local use of hot water, both as a preventive and curative agent in the treatment of gangrene. In wounds with a feeble circulation, low vitality, and disinclination to heal, or with a tendency to gangrene, and in those which are actually gangrenous, there are few agents that act more efficiently as vasomotor stimulants to the injured parts than hot boiled water frequently and copiously applied. There is some art in the use of so simple a thing as hot water. More than forty years ago, in the practice of my old preceptor, the late distinguished Dr. Benjamin W. Dudley, of Lexington, Ky., I witnessed the method of treating all classes of wounds almost exclusively by hot water, and with the most excellent results. His method was the application of hot water that had been boiled and reduced to a temperature of from 110° to 120°. If the healing process was sluggish, or if there was a tendency to slough, the water was applied for from twenty to thirty minutes every one or two hours. The circulation and vital action in the parts rarely failed to improve under this treatment. An interesting illustration in his practice of the effects of applications of water at a temperature of 105° as a preventive of sloughing, was in his treatment of violent purulent ophthalmia. The water, in such cases, was poured on the eye and between the lids from the small spout of a one-pint tin vessel, for from ten to fifteen minutes every one or two hours; and among a number of cases which I saw treated in this manner there was not a single case of sloughing of the cornea. For more than fifty years Dr. Dudley treated all wounds, except those healing by first

intention, with hot water applications, and for more than forty years I have carried out these principles in my surgical practice with good results. Dr. Dudley attached great importance to boiling the water and reducing it to the proper temperature. He had a clear and well-defined idea that to be fitted for this purpose, all animal and vegetable matter should be destroyed by boiling. This is simply what is now termed "sterilized water" and which is universally sanctioned by the profession. He had a conviction that hot-water applications always promoted the healthy condition and healing of wounds, and at the same time prevented ill consequences, such as gangrene. Hence, in his practice, he never used cold water as an application.

I cannot permit this opportunity to pass without paying an humble tribute to the genius and ability of this, one of the greatest surgeons America ever produced. During the war I found hot-water dressings as a means of promoting reaction, as a preventive of gangrenous tendencies, and for improving the condition of unhealthy wounds, invaluable. I could procure hot water when nothing else could be obtained. A camp-fire, a camp-kettle, a tin-cup, and water, gave me a perfect sterilized dressing that was ample to keep wounds clean and healthy.

General treatment.—Can general treatment in any manner aid in arresting the process of gangrene and repairing its ravages? I feel sure that its capabilities in this direction are very considerable. To supply healthy blood in place of that which has been impaired, and to sustain vasomotor action and cardiac force, and, consequently, the general circulation, are the chief objects of general treatment. We have no internal antidote to pyæmia or septicæmia. All antiseptics for this purpose must be of a local character. Iron, quinine, and strychnine are our most important drugs for general treatment. I give the iron in the form of the tincture of the chloride in these cases, in doses of from thirty to forty drops every three hours. It acts as a permanent stimulant to the vasomotor system, improves the nutrient qualities of the blood, and aids in preventing the tendency to collapse. In cases of gangrene or sloughing wounds, in which the exuded blood consisted mostly of reddish serum, I have seen the blood under the use of iron become so rich in red corpuscles, albumin, and fibrin, that a few drops from a granulation would form a firm coagulum. This, to me, is a certain indication that sloughing is about to cease.

In those cases in which the circulation is feeble, the arterial tension low, and the vasomotor action nearly paralyzed, with a tendency to reduction of temperature in the wounded parts, I know of no general agent which gives impetus and force to the circulatory and heat-producing powers so promptly as nitroglycerin in doses of from $\frac{1}{50}$ to $\frac{1}{100}$th of a grain every three hours. In cases of thrombosis of a main artery, when we desire to establish a collateral circulation promptly, I believe that nitroglycerin, strychnine, iron, and strophanthus, are the most effectual means that we possess. In cases arising from embolism with septicæmia, I have found carbonate of ammonium to be valuable in connection with the remedies mentioned. In gangrenous affections, and particularly in extensive gangrene, the tendency to vasomotor paresis and general collapse is very great, and the remedies mentioned have often enabled me to tide over the emergency.

Alcoholic stimulants are indispensable in these cases, but to be of service they must be administered in large quantities. In cases of threatened or actual collapse from gangrene, I have found the system exceedingly insensible to the action of alcohol, and, consequently, capable of receiving large quantities before actual beneficial results are manifested. On one occasion, in a case of gangrene following a gunshot wound, the patient took one quart of whiskey daily, in the forms of milk-punch, egg-nogg, and pure whiskey or punch, before reaction was established. In such cases a good digestion and an abundance of concentrated nutriment are necessary to tide the case over the emergency. During the late war I saw a bad case of gangrene recover on little more than an abundance of whiskey and nourishment and hot-water applications. The patient had a good appetite and took with avidity all that he could get. Inability of the stomach to retain and digest sufficient nutriment to repair the blood depreciation, and maintain vasomotor action, is a great difficulty in the treatment of the septicæmia of gangrene. In this condition life largely depends on a vigorous stomach, plenty of nourishment, and the preservation of the system in an aseptic condition.

To illustrate more clearly the views presented in this paper, I will give in detail the history of certain cases of gangrenous wounds and diseases which have come under my observation at different times.

Case I. *Gangrene of the external genitals in a woman.*—Thirty-two years ago, previously to our advanced knowledge of the antiseptic treatment of disease, I was called to a puerperal case which some days before had been delivered by a midwife. The patient was in indigent circumstances. On entering the sick-room there was an odor pervading the entire apartment so overwhelmingly offensive and fœtid as to create intense nausea and disgust. On examination, after the parts were deodorized with chlorinated soda, I found the entire external genitals enormously swollen, black, and insensible, and from them flowed an intensely offensive ichorous

discharge. The patient was suffering from septic fever, and was greatly prostrated. Although in this case there was extensive gangrene of the genitals, a sanious discharge, and genuine septic fever, there were no indications of true puerperal septicæmia. And yet the atmosphere surrounding this patient had been for days saturated with intensely offensive effluvia. But after the sloughing tissue was removed, a healthy base established, and free suppuration begun, all the symptoms of septicæmia promptly vanished, the breasts began to secrete, and the system returned to its normal condition.

In reference to the treatment of this case, it was found that the disinfectants then in use exerted no effect on the progress of the case more than to modify the sickening odors. The object was to adopt some agent that had the power not only to deodorize, but to disinfect and corrugate or shrink up the sloughing tissue, stimulate healthy action in the parts, and effect separation.

Previously to seeing this case I had had some limited experience with the use of a concentrated solution of sulphate of zinc and dilute sulphuric acid in the treatment of sloughing affections, and determined to use the present opportunity for experimentation with that remedy. A solution containing sulphate of zinc one ounce, water one pint, and dilute sulphuric acid one-half ounce, was freely applied, by means of cotton-wool and a syringe to the gangrenous parts. At intervals of three hours applications of water at a temperature of 120° were made. In thirty-six hours the results were surprising. The enormously-swollen gangrenous genitals, including the labia and nymphæ, from the pubes to the perineum, had sloughed off, leaving a perfectly clean surface, florid, and exquisitely tender to the touch, and all disagreeable odors had disappeared. So soon as this healthy tissue-base had been reached the solution caused intolerable pain, and had to be discontinued. This case recovered without further difficulty.

CASE II. *Gangrenous carbuncle.*—A German saloon-keeper, fifty-eight years old, a habitual beer-drinker, whose general health had been impaired by his habits, was attacked by a carbuncle on the back of the neck, extending from the scalp down to the sixth cervical vertebra. The carbuncle soon assumed enormous proportions, and the entire mass of tissue from the cutaneous surface to the spinous processes of the vertebræ became gangrenous. After a crucial incision much of this gangrenous tissue was removed. The cavity was then freely bathed with oil of turpentine. But it was not until applications of the solution of zinc and sulphuric acid were made that indications of a return of vital action in the parts appeared. Under continuous applications of the solution separation of the sloughing tissues progressed favorably, granulations began to appear, all offensive odors ceased, and abundant suppuration took the place of the offensive ichorous discharge. This patient's general condition was exceedingly unfavorable. His vital powers were greatly depressed, and the prostration was serious; his pulse was frequent, the extremities cold, his complexion sallow, and his appetite was entirely lost. There were evening exacerbations of fever and copious night-sweats. The patient took as freely as possible alcoholic stimulants in the form of egg-nogg and milk-punch; rich broth; the tincture of the chloride of iron in full doses; one one-hundredth grain of strychnine; the same quantity of nitroglycerin; and two grains of quinine every three hours. At night he took one-sixtieth of a grain of atropine for the night-sweats. In a reasonable length of time I had the satisfaction of witnessing a reaction in the general condition of this patient, the reëstablishment of healthy action in the wound, and the formation of a healthy base for the growth of granulations to fill the vast cavity left by the loss of tissue.

CASE III. *Hospital gangrene of the foot.*—The patient was a soldier who had received, in one of the battles near Richmond, a gunshot wound of the foot, producing a compound comminuted fracture of the metatarsal bones. The wound had been treated principally by means of cold-water applications. When brought into my field hospital near Drury's Bluff, the foot presented a dark, brownish-red color, with great œdema, accompanied with intense burning pain and symptoms of septicæmia. The wounded parts were thoroughly cleansed with soap and water, and dressed with hot-water applications. In twenty-four hours genuine hospital gangrene had developed, his pulse became frequent, his temperature rose, his tongue became dry, his appetite was lost, and his mental condition apathetic. (In almost every instance of hospital gangrene coming under my observation, mental apathy, together with an ichorous discharge from the wound, preceded the development of the disease.) The gangrenous process was extending to the ankle, and the general condition was rapidly becoming worse. The hot-water applications were repeated every two hours, and a solution, containing sulphate of zinc two and one-half ounces, dilute sulphuric acid one-half ounce in one pint of water, was applied. The entire foot was enveloped with raw cotton, which was saturated every three hours. Tincture of the chloride of iron in thirty-drop doses, strychnine one one-hundredth of a grain, and quinine two grains, were given every three hours, with the most nutritious diet that could be procured. In about two days the gangrenous parts presented a rather improved appearance. The process had not extended, the surrounding tissues had a better circulation, and there were less inflammation and swelling, and less pain. From that time to the cessation of the gangrene and the commencement of healing the improvement was progressive. The line of separation was established, the sloughs were thrown off, and a healthy basis was established. As soon as the sloughs separated and the healthy surface was exposed, the applications caused intolerable pain and had to be discontinued and a simple dressing substituted. But previously to this separation, while the sound tissue

was protected by the sloughs, the solution caused no pain whatever.

CASE IV. *Hospital gangrene following a wound of the thigh.*—Lieutenant B., a young Confederate officer in the Army of Northern Virginia, received a grape-shot wound, which extensively lacerated the tissues of the thigh, at the battle of Frazier Farm, 1862. The weather was intensely hot, the atmosphere malarial, and the army had been subjected to six days of hard fighting and marching. When the officer was admitted into my field hospital gangrene had set in at the points of entrance and exit of the ball. The skin around the wound was swollen, of a brownish-red color, and exuding a peculiar ichorous discharge. Very soon the surface of the wound became ashy gray and pultaceous. Already septic or pyæmic fever, initiated with a chill, had commenced. There were complete anorexia, mental apathy, and indifference. The patient was isolated under a tent-fly, and in the shade of a tree apart from the camp, and the fresh air permitted to sweep freely over him. The wounded parts were enveloped in raw cotton saturated with the zinc and sulphuric acid solution, and hot water was applied every two hours. He took iron, quinine, and strychnine, and as there was extreme depression, carbonate of ammonium was given at intervals. His diet was nutritious, with alcoholic stimulants in abundance. Under this system of treatment the gangrenous process was arrested in a reasonable time, and the sloughs, which were extensive, became shrivelled and corrugated, and fell off, leaving a healthy surface, while the general system rapidly responded to the improved condition of the wound. Then the zinc dressing, as usual, gave rise to acute pain and was discontinued. This patient recovered in due time and resumed his place in the army.

The last two cases are cited as examples of my method of treating hospital gangrene at that time. While the results of the method were favorable in the majority of cases, in a certain proportion of cases in which septicæmia was intense, with profound depression and exhaustion from army-life, all remedies, including amputation, failed. Yet in these cases, when I could improve vital action in the wound, disinfect the slough and cause the process of separation to begin, even in slight degree, the general system would promptly respond, as if the gangrene were simply a local process for the continuous generation of infective poison, and when the supply was suspended the effects immediately ceased.

CASE V. *Dry gangrene of the lower extremity.*—This, the case of M. R., a furniture-dealer, presents many interesting features. Some years ago the patient had facial paralysis, then for a time suffered from small carbuncles that sloughed to some extent. In February, 1890, the little toe of one foot became rather painfully inflamed, then the tarso-phalangeal joints became swollen, inflamed and painful, resembling rheumatic gout. After two weeks of great suffering a purple spot appeared on the dorsum of the foot, then vesication followed by dry gangrene which extended rapidly over the foot, excepting the plantar surface. The gangrenous process involved the skin, cellular tissue, muscles, and tendons down to the tarsal and metatarsal bones, and also the upper surface of the phalanges. During this protracted and painful process his general health suffered seriously. There were great mental despondency, but a keen desire to live, entire loss of appetite, sleeplessness, feeble and frequent pulse, jaundiced complexion, dry tongue, occasional rigors, evening fevers with night-sweats, and all the indications of septicæmia. At this stage of the case, at the request of the family, Surgeon-General Hamilton saw the case with me, and was so much impressed with its gravity that he regarded amputation above the knee as necessary to save life. This conclusion was reached because we could not discover a trace of pulsation in either the tibial or peroneal arteries. The inferences we drew were that thrombosis of the popliteal artery existed, and that a collateral circulation sufficient to nourish the limb could not be established. The question then arose whether the feeble circulation in the limb below the popliteal space, the pulsation of the femoral artery being perceptible above, was not already carried on by an imperfect collateral circulation. If the latter was the case the degree of circulation which returned to the limb after cessation of the gangrene, was remarkable. When recovery began the granulations were healthy and profuse, and the healing process continuous. The blood issuing from these granulations on the slightest touch was florid and coagulated rapidly, whereas before, only a dark, reddish serum escaped. Up to the present time no pulsation can be detected in the arteries of the leg.

If we were correct in the conclusion that there was occlusion of the popliteal, this case illustrates to a remarkable degree the powers of nature in establishing a collateral circulation of sufficient force to heal extensive wounds and support the entire limb. My patient was so resolutely opposed to losing his limb that I determined to resort to every resource of surgery to save it. My first procedure was to remove or dissect away with knife and scissors all loose sloughing tissue, including skin, muscles and tendons. Then the entire gangrenous surface was enveloped in absorbent cotton saturated with the zinc and sulphuric acid solution for the purpose of stimulating renewed vital action in the parts, and arousing vasomotor action and sensation. The first indication of a return of sensation in the parts was after these applications. The extensive diseased surface began to assume a more healthy appearance, but now the pain from the application on certain parts became intense, while in some directions the gangrene was extending toward the plantar region. A solution of bromine was then substituted. This solution was exceedingly soothing and at the same time it proved an active stimulant of vital action, and a potent disinfectant, and exerted a decided influence in controlling the infectious inflammation. At times the gangrene ceased, and the remedy was suspended. Localized gangrenous in-

flammation would then return, but the bromine again arrested this inflammation, and stimulated the growth of healthy granulation. I have invariably used the bromine in the strength of two drachms to twelve ounces of water.

The diseased foot was bathed in sterilized hot water every three hours, after which the bromine was applied. Over this an ointment composed of ichthyol three drachms, iodoform one drachm, carbolic acid ten drops, and cosmoline one ounce, was applied. The patient steadily improved under this method of treatment, but became dissatisfied with the offensive odor of the ointment, when the following was substituted: aristol one drachm, vaseline six drachms, lanolin two drachms. This acted well throughout the subsequent course of the case.

I desire to dwell at some length on the value of the agents used in this case not only in arresting the extension of gangrene, but in controlling that type of septic or infectious inflammation which usually precedes the death of the tissues. Hospital gangrene and the gangrene of erysipelas are well known to be infectious diseases, and infection is generated by the peculiar inflammation. The action of bromine in controlling hospital gangrene is manifestly due to its wonderfully energetic disinfectant powers.

In regard to the general treatment of this case of dry gangrene, every means was used for the purpose of improving and promoting blood-formation and nutrition with a view to counteracting the depressing effect of septicæmia. The patient took the most nutritious and concentrated food with an abundance of stimulants, and the traditional triple compound, iron, quinine and strychnine, in connection with one one-hundredth of a drop of nitroglycerin every three hours. Beginning with a feeble cardiac action, low arterial tension, cool extremities, lividity of complexion and feeble circulation in the diseased limb, the action of the heart gained force under the influence of these agents, the arterial tension greatly increased, the complexion improved, and the circulation about the diseased tissues became far more active. Healthy granulations began to form and the sloughs to separate and fall off, and under the disinfectant action of the local agents the septicæmia disappeared. Thus there was a collateral circulation established of sufficient force to enable the system to arrest the gangrene, throw off the dead tissues and begin the process of healing.

As a vasomotor stimulant and a means of invigorating the action of the heart and developing the capillary circulation, I am satisfied that nitroglycerin played a conspicuous part. The periosteum of the upper surface of the metatarsus of a portion of the tarsus, and of all the bones of the toes and their joints, were bared by the sloughing. Notwithstanding this, the profuse and rapidly-growing granulations finally covered most of these exposed bones. The chief difficulty occurred in the articulations, most of which became necrosed. The necrosis at different points was treated by applications of officinal dilute muriatic acid. I have found this, after experimenting with various agents, the most certain and effectual application to cause disintegration of the necrosed bone. Under its action the dissolution and disintegration of the phosphates and carbonates of lime of the necrosed bone progress with surprising rapidity. Necrosed bone contains but little animal matter, hence the acid has a fair opportunity to act. Occasionally since the recovery of the patient, small points of necrosis appear over the formerly-exposed bones through limited ulcerations in the cicatrix, and are successfully treated by means of the dilute muriatic acid.

CASE VI. *Gangrenous phagedæna of the penis.*—In this case gangrene was caused by a chancroid. When the patient came under my charge there was enormous œdema of the prepuce and glans, and the parts were black, pultaceous, and rapidly breaking down. The discharge was of an ichorous and extremely offensive character. Hot-water dressings were frequently applied, and the parts were enveloped in absorbent cotton saturated with the zinc and sulphuric-acid solution, heretofore mentioned, and renewed every three hours. The patient was given the tincture of the chloride of iron and dilute hydrochloric acid every three hours. In due time the offensive odors disappeared, the state of vital action in the parts improved, and the sloughs, under the influence of the zinc and acid applications, contracted and separated from the sound tissues. All of the prepuce, a portion of the glans and the skin on the dorsum, which was gangrenous, sloughed and left a perfectly healthy basis for granulation and the process of healing was accomplished in a reasonable period.

In this paper I have endeavored as far as practicable to describe cases representing the various forms and types of gangrenous affections, and the treatment found most efficient in each variety.

In conclusion, it may be stated, that to attain any degree of success in the local and general treatment of gangrenous wounds and diseases, it is absolutely necessary to discriminate between the various forms of the disease, also to determine the proximate cause and the general state of the patient. There are types of cases purely septic in origin in which sublimate dressings are applicable. There are other cases strictly of an infectious origin, upon which nothing acts better than bromine. Again, there are cases, whether of a traumatic or idiopathic form, in which vital action and vasomotor power are reduced to the lowest degree, and in these cases the strong solution of sulphate of zinc and dilute sulphuric acid acts well.

PRELIMINARY NOTES ON A CASE OF LUPUS VULGARIS TREATED BY INJECTIONS OF KOCH'S LYMPH.

BY JAMES HENDRIE LLOYD, M.D.,
AND
HENRY W. STELWAGON, M.D.,
OF PHILADELPHIA.

THIS case occurred in the practice of Dr. Lloyd four years ago. It was subsequently seen in consultation by Dr. Stelwagon, who, in view of the small size of the patch, operated by excision. A recurrence lately taking place, it was decided, after due consideration and upon the solicitation and acquiescence of the patient's parents, to treat the disease by the method brought forward by Koch. The injections were made at the boy's own home. The case is still under treatment and observation. The newness and great interest in this method justify the publication of these preliminary memoranda.

When the patient first came under our conjoint observation, two years ago, the patch of disease, situated on the left cheek near the angle of the jaw, was about the size of a small bean. It consisted of several closely contiguous characteristic lupus tubercles or deposits, with no tendency to ulceration, but with a slight disposition to exfoliation. It had then existed for at least six years, beginning when the boy was five years old. The result of the operation referred to above was apparently good, healing rapidly ensuing, and the disease exhibited no tendency to recur until nine months ago. At this time points of lupus-deposit began to show at the edges of the cicatrix, and have since progressed slowly. Two weeks ago, when Koch's treatment was begun, the whole patch was slightly elevated, and consisted of an oval-shaped scar, somewhat reddish, and with the peripheral portions studded with several small tubercles; each of these latter was covered with a minute scale.

The patient is a well-grown boy of fifteen years, a native American, well nourished and robust. No indication of tuberculous disease elsewhere in the body exists. The family history, however, is tuberculous.

Since the first injection the temperature and pulse have been recorded every two hours.

First injection, January 8th, 0.001 gramme of lymph. No systemic reaction. The patch showed but little, if any, reaction; it was possibly slightly more elevated and reddened.

Second injection, January 10th, 0.001 gramme of lymph. Slight chilly sensations four hours later, but no rise or fall of temperature. On the day following the patch was somewhat elevated, puffed, and reddened. The points of disease were not so prominent, this probably being only apparent and due to the increased elevation of the central scar-tissue. Two minute foci, not before seen, could now be detected at the edge. On January 12th the swelling and redness had somewhat diminished.

Third injection, January 13th, 1 P. M., 0.002 gramme of lymph. At 10 P. M. a severe chill, lasting a half-hour, accompanied with headache and aching of the bones, etc. The temperature rose rapidly until it reached 102.5° at 2 A. M. on the following day (January 14th). It then sank with some fluctuation to 101⅕°, rising again to 102⅖° in the afternoon. The area of disease became decidedly puffed, prominent, and red.

On the next day (January 15th) the temperature fell to 97°. The patient's general condition was good. The whole patch, including the scar-tissue, was paler. The scar was covered with scanty bran-like scales, the lupus-points were flatter and covered with a thin crusty-looking scale.

On January 16th the scaliness had become much more abundant, and directly over the lupus-deposits partook more of the nature of crusts than scales; the patch was pale pink and the puffiness completely gone. Over the trunk posteriorly a small papular, discrete and patchy, pink to red, measley-looking eruption was visible.

Fourth injection, January 16th, 12 noon, 0.002 gramme of lymph. Temperature three hours later was 97°. The rise began at 3 A. M. on the following day, reaching 101⅖° at 11 A. M., and toward evening falling to normal. The patch was now (January 17th) covered with much more copious bran-like scales, and was surrounded by an erythematous zone. The measly eruption on the back was brighter and more diffuse.

On the next day (January 18th) the temperature was more markedly subnormal than at any time during the treatment, falling to 96⅖°. At this time the pulse was 58. The patch of disease was apparently becoming less conspicuous and flatter.

Fifth injection, January 19th, 5.30 P. M., 0.002 gramme of lymph. Temperature began to rise at 4 A. M. on the next morning (January 20th) and reached at noon 103⅕°, at which time the pulse was 116, but of good force. No eruption on back. No chill. A feeling of nausea. The patch had a markedly-shrivelled and sunken appearance, with a pinkish flush surrounding it.

SUMMARY.—The patient has borne the injections well. There have been no alarming symptoms at any time. The dose has not been increased beyond 0.002 gramme, inasmuch as the reaction following each injection of this amount has been considered sufficiently intense. The sites of injection for the diameter of an inch or so become slightly reddened, the flush then gradually disappearing; at the site of the first injection the erythematous patch has remained, but in other respects nothing is to be noted.

The patch of lupus has been undoubtedly impressed, and, we think, in a decided and favorable manner; the diseased area being apparently less elevated and less conspicuous than before the injections were begun. The puffiness, prominence, and redness which followed the first three injections have been absent in the last two; in these last the result has been an increase in the exfoliation, and the appearance of an erythematous zone surrounding the patch. This zone disappears slowly during

the twenty-four hours following the injection. It is, of course, too early in the treatment to state the probable result. So far it has been sufficiently encouraging to warrant a continuance of the injections.

MEDICAL PROGRESS.

Pilocarpine in Diseases of the Ear.—Since 1880, POLITZER (*Lancet*, January 3, 1891) has employed subcutaneous injections of muriate of pilocarpine in every variety of recent and of chronic affections of the labyrinth, often with excellent results. He uses a two-per-cent. solution. At first two drops of this are injected under the skin of the arm, and the dose is increased by one drop each day until eight drops are given at an injection. Soon after the injection there is increased secretion of saliva and sweat for about forty-five minutes. If there are disagreeable effects, such as nausea, giddiness, faintness, etc., they may be overcome by the administration of a small dose of atropine. The injections should be made daily. If, after two weeks, the remedy does not produce an improvement of hearing, it must be regarded as ineffectual, and should not be continued; but if the hearing improves, the injections should be continued as long as the improvement progresses.

Dr. Politzer summarizes his opinions as follows: 1. The subcutaneous injection of pilocarpine is particularly indicated in recent affections of the labyrinth, be they syphilitic or not. 2. The injections are of little use in acute inflammation of the middle ear. 3. They are decidedly contra-indicated in cases of dry sclerotic catarrh of the middle ear. 4. Injections of several drops of a two-per-cent. solution into the tympanic cavity through a catheter are beneficial in some cases of catarrh with swelling and slight secretion. In such cases the injections should be given for from one to two weeks alternately with Politzer's method of inflation.

Ointment for Comedones.—The *Canadian Pharmaceutical Journal* quotes the following prescription, said to be used by Unna in the treatment of comedones:

℞.—Solution of hydrogen peroxide, Vaseline } of each 2 ounces.
Lanolin . . . . . 1 ounce.
Acetic acid . . . . . 1 drachm.
Mix and perfume.

Treatment of Laryngeal Spasm.—The treatment of spasm of the glottis is often difficult and uncertain in its results, but SIR MORELL MACKENZIE writes that by setting up a rival reflex the laryngeal spasm may be instantly overcome. The patient need only take a pinch of snuff or black pepper into the nostrils, or if neither can be obtained the nares should be tickled by a feather. The immediate result is a paroxysm of sneezing, after which the breathing is relieved.—*Hospital Gazette*, December 6, 1890.

The Administration of Oxygen by the Rectum and Hypodermically.—DR. FRANCESCO VALENZUELA, of Spain (*El Siglo Médico*), has published a paper on new methods of administering oxygen with especial reference to the treatment of senile pneumonia. Believing that oxygen inhaled in dyspnœa frequently fails to relieve because it does not come in contact with a sufficiently large vascular area, he began administering the gas *per rectum* and also hypodermically. In every case in which oxygen enemata were given dyspnœa was decidedly and permanently relieved. The ease and rapidity with which the gas was absorbed by the intestine were remarkable; indeed, it seemed to be as readily taken up by the intestine as by the lungs, four injections of five litres each being absorbed in an hour. Thus the intestinal mucous membrane may become a valuable adjunct to the lungs. In employing oxygen hypodermically Dr. Valenzuela believes that it is important to introduce the gas in its nascent taste. The arm was selected for the injections, and the quantity of gas introduced varied from half a litre to a litre. Cellular emphysema was, of course, produced, and a sensation of heat was complained of, but both disappeared within a few hours. There was no calmative action or slowing of the respirations, but there was marked stimulation of the heart, a desirable result in the collapse that follows pneumonia and fevers of a typhoid character, and cerebral congestion and asphyxia. No mention is made of the temperature of the gas that was administered, a point which, according to Dr. B. W. Richardson, is of great importance.—*Lancet*, January 3, 1891.

Treatment of Uterine Catarrh.—The *Revue Obstetricale et Gynécologie* (December, 1890) gives the following treatment for catarrh of the cervix uteri. After stating that it is best to have a syringe which will deliver the stream in jets, and that the injections should be repeated twice a day, the following medicated solution is valuable. These solutions may be either antiseptic or astringent. A useful antiseptic solution is to be made by taking 4½ ounces of boracic acid and dividing it into 10 powders, one of these powders is to be placed in 3 pints of boiling water; or, with equal advantage, we may employ 10 drachms of the sulphate of copper, which are to be divided into 10 powders, and one of these powders placed in 3 pints of boiling water; or, again, 2½ drachms of beta-naphthol may be added to 8 ounces of alcohol. Of this last solution, a teaspoonful is placed in a quart of boiling water; as soon as the water is cooled to a temperature of about 105° or 110°, it may be injected. In other cases, 4½ ounces of borate of soda may be divided into 10 packages, and the contents of one package be added to 3 pints of boiling water; or in its place may be employed 15 grains of nitrate of silver dissolved in 3 ounces of distilled water, of which a dessertspoonful is to be placed in 3 quarts of boiling water. In other instances from 20 to 100 drops of a solution of the perchloride of iron may be added to 3 pints of water and used instead of the solutions already named.

Prescription for Hemicrania.—In the *Journal de Médecine de Paris* the following prescription for hemicrania is given:

℞.—Antipyrine . . . . 3 grains.
Antifebrin, Powdered rhubarb } of each 1 grain.
Powdered calamus . . . ½ "
Powdered quinine . . . 1 "

This is to be made into 1 powder and repeated three or four times a day if necessary.

CURRENT LITERATURE.

DIAGNOSIS AND TREATMENT OF TUBAL PREGNANGY IN THE EARLY STAGE.

SMOLSKY calls attention to the fact that the teaching on ectopic gestation has undergone some changes during recent years. He claims that extra-uterine pregnancy occurs more frequently than was formerly supposed. According to M. Veit, nearly 28 per cent. of all cases of retro-uterine hæmatocele are due to tubal pregnancy with rupture of the sac. He recognizes the existence of ovarian and ovario-tubal gestations, but expresses doubt upon the possibility of peritoneal pregnancy. The tubal form is the gravest and the most frequent. Its gravity consists in a very considerable percentage of mortality, and in the possibility of sudden death. In the early months of tubal gestation the diagnosis is very difficult and often impossible, since most of the patients die during this period from a rupture of the embryonal sac with profuse hæmorrhage. He believes that more importance should be accorded to the form of the uterus than is usually done by writers upon the subject; of all the works he has examined Ernst Fränkel alone makes mention of this. As regards the size of the fœtal sac in tubal gestation, Smolsky has found that during the second month it attains the size of a pigeon's-egg; at two months it is as large as a walnut; at two and a half months as large as a hen's-egg; at three months it reaches the size of a fist, and at four months two fists. The signs of pregnancy, the metrorrhagia, the atypical pains, the insufficient development of the uterus with a parallel enlargement of a tumor on either side, the form of the womb, which is flattened in the antero-posterior diameter, the ineffectual contraction of the uterus without dilatation of the uterine canal, the consistency of the tumor, and the vascular bruit, are the diagnostic signs of this condition. The spontaneous discharge of the decidua he regards as of very important, but not decisive signification.

He draws the following conclusions from the information he has been able to gather from the literature on the subject:

1. The precise diagnosis of tubal gestation can be established by clinical examination. A sure way consists in careful and repeated explorations with comparison of their results.

2. In the present state of our knowledge, in most of the cases an absolute diagnosis is scarcely possible before the third month.

3. It is unnecessary and dangerous to use exploratory instruments, such as the sound and curette, in the uterine cavity to diagnose tubal pregnancy in its initial stages.

4. With a suspicion of tubal gestation and the appearance of a tumor on the side of the womb, in cases difficult of diagnosis, an exploratory laparotomy is admissible.

5. In case of the positive diagnosis of tubal gestation before the rupture of the sac, the best treatment is extraction of the sac by laparotomy.

6. In case of rupture laparotomy must be considered as obligatory, if the state of the patient gives rise to anxiety.

7. In case of completed tubal pregnancy it is necessary to take into consideration the life of the fœtus in fixing the time of operation.—*Archives d'Obstetrique et de Gynecologique*, December 25, 1890.

INTRA-UTERINE TAMPONMENT.

IN a communication read before the International Congress at Berlin, in August last, DR. AUVARD, of Paris, endorses Dührsen's method of tamponing the cavity of the uterus for the arrest of hæmorrhage arising from uterine atony. He claims that it is attended with but slight danger, and that its efficacy is generally recognized by the accoucheurs who have employed it. It should, however, not be employed until intra-uterine injections of hot water and subcutaneous injections of ergot have proved inefficient. The method of procedure is as follows:

The woman being placed across the bed (a vaginal douche having been previously given), with the aid of volsella forceps the anterior lip of the cervix is seized and brought down to the orifice of the vulva, whilst at the same time an assistant presses upon the fundus of the uterus to favor its descent. The cervix is then inspected to be certain that it is not the source of an arterial hæmorrhage, in which case a ligature should be placed around the bleeding vessel. The cervix being held at the vulva, the uterine cavity is abundantly flooded to favor the escape of the clots which it contains, and which should be, in difficult cases, removed with the fingers; this manœuvre is easy if care is taken to press simultaneously upon the fundus of the uterus. When the uterine cavity is free, the operator carries into it, by the aid of forceps or the fingers, the end of a strip of iodoform- or simple gauze (the latter should be previously soaked in boiling water for some minutes, or in a sublimate solution of 1 to 1000, and then carefully squeezed dry). The forceps, or fingers, are then withdrawn and a new portion of the gauze inserted, and this is repeated until the cavity of the uterus is filled. Before detaching the volsella forceps, the cervical canal should also be filled. Then, the cervix being freed, as much gauze as possible is introduced into the vagina; in a word, not only an intra-uterine tamponment is made, but also an utero-vaginal tamponment, which is surer. This tampon should be left in place twelve hours, a sufficient time for the hæmorrhage to cease.

Should the hæmorrhage be very grave, the procedure is somewhat different. The hand should at once be introduced into the uterus, the woman having been placed in the obstetrical position. Then, abandoning the fundus of the uterus to the care of an assistant, after having emptied the cavity of the uterus of its contents, the free end of the strip of gauze is passed up into the cavity by the aid of forceps, or by the fingers of the left hand, and

grasped by the fingers of the hand already within the cavity of the uterus, and carried to the fundus; successive portions are thus introduced until the cavity is filled, when the utero-vaginal tamponment is performed as already stated. If properly done this method of arresting uterine hæmorrhage is very efficient, and, with ordinary care, is not attended with any bad results.—*Archives de Tocologie*, Dec. 1890.

LOSS OF CONSCIOUSNESS IN EPILEPSY.

Brown-Séquard asserts that in epilepsy, as in natural sleep, it is beyond doubt that cerebral anæmia is not the cause of the loss of consciousness, but that it is extremely probable that the cessation of the activity of the brain in sleep, either hypnotic or normal, in *petit mal*, in a well-developed epileptic convulsion, in certain cases of syncope, in asphyxia, and in poisoning, depends upon an inhibitory action upon the base of the encephalon and cervical marrow, without the quantity of blood being diminished in the brain. He has demonstrated this inhibitory action by several experiments upon dogs and other mammals, the mere section of the skin of the neck, which it is necessary to make in order to expose the great sympathetic and its ganglia, being followed by an inhibition of the epileptogenous power of the brain, whilst ablation of the two superior cervical ganglia is followed by the same inhibitory action, the quantity of blood in the brain remaining normal.—*Archives de Physiologie*, January, 1891.

ACTION OF CERTAIN REAGENTS UPON THE CEREBRAL CIRCULATION.

De Boeck and Verhoogen have published some observations upon their studies of the modifications in the cerebral circulation which take place under the influence of certain reagents. Their investigations included the effects produced by carbonic-acid poisoning, and those arising from subcutaneous injections of ether or intravenous injections of morphine, with special reference to their influence upon the general blood-pressure, the force of the cerebral circulation, as shown by the quantity of blood traversing the brain in a given time, and the effect upon the cortex and basal ganglia. These experiments were performed for the most part upon curarized dogs, and consisted in the introduction of a canula, armed with a glass tube, into the external jugular vein after ligation of all the veins emptying into it with the exception of the inferior cerebral, thus securing the escape of all the blood through this channel. By the aid of the kymographion they were enabled to estimate the force and rapidity of the cerebral circulation, and to note any changes arising from the introduction of the poison into the system. The general blood-pressure was taken in the right crural artery. By means of ophthalmoscopic examinations these observers were enabled to note the effects of the substances upon the basal circulation, while the thermo-electric needle recorded any alteration in the cortical temperature as indicative of changes in the circulation there.

A condition of *asphyxia* was produced either by arresting the artificial respiration in the curarized dog, or by compressing the trachea when the animal was breathing naturally. The circulation under these circumstances became more active in every part of the brain, and this augmentation was independent of the changes in the general blood-pressure. An active cerebral congestion was produced, as shown by the ophthalmoscope and thermo-electric needles.

It was found that sulphuric ether injected under the skin of the breast or abdomen slightly raised the general arterial-pressure, and at the same time produced an increase in the flow from the cerebral vessels.

From the experiments upon the action of morphine, it was found that the hydrochlorate administered intravenously weakened the cardiac contractions and dilated the capillaries, but did not alter the cerebral flow. After a single injection the arterial-pressure remained normal during a period of time varying from a few seconds to a half-minute. It then fell abruptly, remaining low for a period of variable duration, and then slowly returned to its normal level. The effects of successive injections became less and less marked, until scarcely any appreciable fall was noticed. Sooner or later, however, according to the susceptibility of the animal, sudden irregularities occurred in the kymographic curve, succeeding one another quickly, or separated by regular tracings. Upon the cerebral circulation the effect was very interesting. The cortex became anæmic, while the base became relatively hyperæmic.

Practically these experiments with morphine are suggestive. From the depressing effect of the drug upon the heart and circulatory system, it is evident that its subcutaneous use is contra-indicated in lesion of the heart and vessels, in atheroma, and in cardiac asthenia. The effects are entirely opposite to those produced by digitalis. Morphine is, therefore, of service where digitalis fails, preëminently in great hypertrophy of the left ventricle, in which it weakens the cardiac contractions, dilates the vessels, and regulates the circulation.

The authors append the following *résumé* of their work:

1. In an artery which divides into two systems or branches, if the capacity of the branches is not approximately proportionate to that of the common trunk, every variation in the resistance to the passage of the blood in one of these networks determines the variations in the flow of the other.

2. This reciprocal dependence of the capillary circuits fed by the same artery is much more marked if the distance between the collateral and terminal networks is great. This rule holds with great force in regard to the cerebral circulation.

3 In poisoning by carbonic acid the blood-pressure rapidly rises, the cerebral flow becomes more abundant, and the circulation of the base and of the cortex becomes more active.

(*a*) Following subcutaneous injections of ether

the blood-pressure slightly rises; the cerebral flow increases little by little; and the blood-supply is more abundant to every part of the organ; but these phenomena are slighter and less evident than those produced by asphyxia.

(*b*) Intravenous injections of morphine lower the blood-pressure; the cerebral flow does not undergo modification, but there is anæmia of the cortex with hyperæmia of the base.—*Journal de Médecine*, November 5, 1890.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, December 4, 1890.

J. EWING MEARS, M.D., IN THE CHAIR.

(Concluded from page 83.)

DR. JOHN B. DEAVER read a paper entitled

OPERATIVE TREATMENT OF STRICTURE OF THE MALE URETHRA.

His objects, he said, in reading a paper upon this subject were, first, to present the treatment that he has found most satisfactory and which he believes offers the only means of cure in the great majority of cases as he has demonstrated most satisfactorily to himself; second, to detail some of the consequent conditions, especially those following strictures of large calibre; and third, to provoke discussion, and thus to hear the experience of others.

To make the subject as concise as possible he classified strictures under the following heads: 1st. Strictures of large calibre. 2d. Strictures of small calibre. 3d. Impermeable strictures.

Any of these forms might be the result of disease, which is more common, or of traumatic origin, which is less common. The larger number of the former, in the speaker's experience, are in the pendulous or spongy urethra, from two and one-half to three and one-quarter inches within the meatus; traumatic strictures being almost always of the membranous urethra.

If the stricture is twenty millimetres or more in circumference the diagnosis is best and most accurately made by the urethrometer and urethroscope, and if less than twenty millimetres in circumference with the *bougie à boule* and the urethroscope.

Strictures of large calibre and contractions of the meatus show their ill effects chiefly by reflex troubles of the urinary and sexual apparatus, and cause, first, the simplest of these troubles, namely, retention of a few drops of urine in the urethra after urinating, due to spasmodic contraction of the muscular layer of the urethral wall; second, painful and prolonged erections immediately preceding or following urination; third, a contracted and somewhat hardened condition of the penis due to spasmodic contraction of the muscular fibres embedded in the trabeculæ of the corpora cavernosa; fourth, retention of urine due to spasmodic contraction of the compressor or constrictor urethra muscle—spasmodic stricture (termed urethrismus by Otis) in which in some cases it is not only difficult but may be impossible to introduce an instrument into the bladder, even when the patient is under the influence of an anæsthetic; fifth, cystospasm, and at times associated with it, rectospasm; sixth, chronic urethritis, which can be determined only by a urethroscopic examination; seventh, reflex sensory neuroses, which in too many instances make the patient's life a most miserable one, and to the existence of which every experienced neurologist can bear witness.

Many a patient suffering from a reflex sensory neurosis, caused by a stricture of large calibre or a contracted meatus, describes a train of symptoms which the surgeon, whose advice he seeks, stamps as hypochondriacal, confirmed dyspepsia, neurasthenia, etc., and dismisses as incurable. When such a case passes into the hands of another surgeon, and the cause of the trouble is detected and corrected, the latter gentleman is said, by those who are sceptical upon the subject of reflex neuroses produced in the above-mentioned manner, to have cured the patient by the moral effects of the operative procedure.

Dr. Deaver then read a letter from a former patient of his, a physician in the far West, who came to Philadelphia and placed himself under the care of two prominent surgeons, both of whom are members of the Academy of Surgery. Both surgeons finally told the patient that he was free from any organic trouble, and that it was only necessary for him to exercise the proper amount of will-power, when things would right themselves. The man, before leaving Philadelphia, consulted the speaker, who learned that in early life he had been addicted to the practice of masturbation. He examined the urethra with the urethrometer, and found both a contracted meatus and a stricture of large calibre. He operated, and ten days later the patient went home.

Symptoms of obstruction occasioned by a stricture of large calibre or by a contracted meatus are rarely so pronounced as to induce the patient to seek advice.

The disturbance of the sexual apparatus, brought about by a stricture of large calibre or by a contracted meatus, manifests itself chiefly by impotence, and particularly by the variety known as impotence due to weakness with abdominal irritability. These symptoms are explained by the stricture or contracted meatus exciting reflex irritation of the prostatic urethra; this portion of the urethra being surrounded by the prostate gland, in the superficial as well as the cortical layers of which are extensive nerve plexuses interspersed with ganglia to which belong, among other functions, that of reflexly exciting erections.

The conditions ascribable to strictures of small calibre, and to impermeable strictures, are so familiar that the speaker did not detail them, but simply said that obstruction and its results are what interfere with the entire urinary apparatus of these subjects.

It is the speaker's practice, in dealing with strictures of large calibre, to restore at once the urethral calibre by dilating internal urethrotomy. A contracted meatus is divided with the meatotome. The urethrotome which he uses is that of Otis, with his own modification of the blade. This instrument is as superior to all other urethrotomes as the urethrometer is superior to the bulbous bougie.

The different forms of treatment made use of in stricture include gradual dilatation, continuous dilatation,

rapid dilatation or divulsion, internal urethrotomy, external urethrotomy, and perineal section.

In a paper upon the same subject, published in the *Therapeutic Gazette*, October 15, 1890, the speaker recorded his objections to treatment by gradual, continuous, and rapid dilatation, to divulsion, and to internal urethrotomy with the Civiale urethrotome. Passing the bougie into the bladder, and necessarily over the prostate, when practising dilatation for stricture, the most common seat of which is the pendulous or spongy urethra, is the usual practice, and, he believed, should be most strongly condemned. In cases that he is compelled to treat by gradual dilatation he simply introduces the instrument beyond the stricture, and never further than the bulbo-membranous junction, except in cases of stricture of the membranous urethra, which are very rare. He uses for this purpose a conical steel sound, shorter and less curved than the ordinary sound.

The only proper operations to obtain a radical cure of stricture of the male urethra are, in the speaker's judgment, gradual dilatation, practised only as a preliminary procedure to dilating internal urethrotomy; dilating internal urethrotomy; internal urethrotomy with the Maisonneuve instrument, and external urethrotomy or perineal section. By external urethrotomy he meant an opening made into the urethra from without and anterior to the perineo-scrotal junction, and by perineal section he meant opening the urethra from without but posterior to the same junction.

He wished it clearly understood that he restricts the operation of internal urethrotomy, done either with the dilating urethrotome or with the Maisonneuve instrument, to strictures not further back than four and one-half inches in a penis of medium length, and five inches in a very long penis.

He highly approves of using either a general or local anæsthetic in internal urethrotomies, and gives decided preference to the former, as, other things being equal, he believes that our work is done better when we have the complete control of the patient; and again, we are not as likely to hurry with the operation as we are when using a local anæsthetic, which may entirely anæsthetize the parts, but does not abolish the patient's apprehension, as a result of which he becomes nervous and anxious, soliciting the surgeon to stop before all traces of obstruction are entirely relieved.

The question of urethral antisepsis is very important in connection with the subject of internal urethrotomy. This consists of the administration of boric acid internally for three or four days before operating, and of flushing the urethra for the same length of time from four to six times daily with a 1-to-10,000 or 1-to-15,000 solution of bichloride of mercury. The speaker believes that it is of special importance to introduce an aseptic soft-rubber catheter into the bladder immediately after the operation and to retain it for twenty-four hours. If there is any doubt that the urine is aseptic, it is well to wash out the bladder through the retained catheter with the 1-to-15,000 solution, or, if the operator prefers, with boric acid solution. The strict observance of the foregoing treatment, in addition to thoroughly clean instruments, renders this operation positively free from risks, granting that the operator is familiar with and recognizes any of the contra-indications to the operation.

In strictures of small calibre not deeper than four and one-half inches in a medium-size penis, and five inches in an unusually large penis, he cuts to 20 millimetres with the Maisonneuve instrument, completing the restoration to the normal calibre with the dilating urethrotome.

Strictures of small calibre deeper than five inches he cuts from without, doing either an external urethrotomy or a perineal section, depending upon the location of their stricture.

Impermeable strictures call for either external urethrotomy or perineal section, depending upon their location. Impermeable strictures, when multiple, and also a very long linear stricture, may require both external urethrotomy or perineal section and internal urethrotomy. In some cases it is impossible to pass the filiform bougie of the Maisonneuve urethrotome through the stricture by the way of the meatus after having done an external urethrotomy or perineal section, and in order to complete the operation it is necessary either to prolong the external wound until all of the strictured area is divided, or do an internal urethrotomy. In such cases he has succeeded in passing a very fine-eyed probe through the stricture from behind forward, introducing it by the way of the wound. He has then tied to the probe small knives like those of the Maisonneuve instrument, drawing them after the probe through the urethra and out from the meatus, in this manner cutting the stricture or strictures to 20 millimetres. It then only remains to complete the division with the dilating urethrotome.

Both external urethrotomy and perineal section the speaker performs without a guide, placing more reliance on the recognition of the tissues than upon any mechanical assistance. Some surgeons speak of doing the operation in the above manner as plodding one's way into the urethra. This is certainly a just criticism when applied to a surgeon who is not a surgical anatomist. But even where the perineum is greatly infiltrated he has not experienced any difficulty, as the exposure of the healthy urethra immediately anterior or posterior to the obstruction is the most reliable guide to the diseased portion. Having completed the operation, he not only introduces a drain into the bladder through the wound but also through the urethra, by which means he is able to irrigate the bladder and the urethra separately.

Suprapubic drainage as a preliminary to perineal section or external urethrotomy, in certain cases of stricture of small calibre and of impermeable strictures, may be required owing to the presence of complications rendering immediate perineal section or external urethrotomy inadvisable.

In discussion, DR. MORTON said that after listening to the paper and having before him a great array of instruments, said to be absolutely necessary in the successful treatment of urethral stricture, it would seem either that he was behind the times, or that he has not had under treatment those forms of stricture to which the attention of the Fellows had been called. In his long experience in private and hospital practice, he had never seen a case of stricture which required internal urethrotomy; consequently he has never performed the operation, and yet he is satisfied that his patients have been cured. He recognizes but two forms of stricture, the permeable and the impermeable; the former he can generally dilate,

in the latter he always makes a perineal section. In dilating strictures he invariably uses either graduated steel bougies, or first stretches the stricture with the Wakling tubes, introducing first the smallest silver instrument, when dilatation can be readily and safely effected by the introduction of larger tubes. The subsequent treatment consists in the passage of steel bougies, with the use of which the patient is made familiar.

In those cases of permeable strictures which, although a small instrument can be passed, present great irregularity and rigid walls, he prefers perineal section to dilatation. After perineal section he introduces the short, straight silver tube in the bladder and drains through the wound for a few days, after which a catheter or a steel bougie is daily passed through the entire urethra, gradually increasing the size of the instrument.

DR. HUNT agreed with Dr. Morton, and although he had had no experience with the method suggested by Dr. Deaver, he could claim a fair measure of success. He has discharged such patients, comparatively speaking, well, having taught them to use the instrument themselves; but we all know how careless people are of such matters. He has seen strictures return after external urethrotomy, and thought that he could not give a better report of those treated by dilatation. He has frequently performed the external operation, but very rarely the internal.

DR. PORTER, while he endorsed a great deal that Dr. Deaver had said, could not go so far. He was never partial to internal urethrotomy, his preference being for gradual dilatation with bougies. He believed that we can cure these cases as completely by gradual dilatation as by internal or external urethrotomy. The secret of success is dilatation to the normal calibre of the urethra. He does not like filiform bougies, as it is impossible to tell where the bougie goes. He has seen a filiform bougie apparently pass without difficulty, but when it was withdrawn it was found to be doubled on itself. He uses in preference the finest steel bougie, the position of the handle indicating where the instrument is. He has had as difficult cases as anyone to treat, and has seen no reason to find fault with gradual dilatation. About eighteen months ago a man was brought to his office with an exceedingly tight stricture. His history was that he had only urinated in drops for more than twenty years. The speaker worked with the fine steel bougies for some time, and finally succeeded in passing a No. 2 (French). He allowed this to remain a few seconds, and then followed it by No. 3 and then by No. 5. He then introduced the smallest catheter that he had and emptied the bladder. The patient was told to go to a hotel and to bed. He returned every three or four days and had the instruments passed, and in three months was cured. If we dilate to the normal calibre of the urethra, Dr. Porter does not believe that the stricture will return. He has examined several cases, some years after the cessation of treatment, and, as a rule, there has been no relapse.

He could endorse everything that Dr. Deaver said in regard to nervous troubles from strictures of large calibre but could not agree with him in the methods of treatment. He has never done internal urethrotomy, and external urethrotomy only rarely, for he seldom fails to relieve retention of urine by passing an instrument through the urethra. If he failed to empty the bladder by a catheter, he would aspirate. The latter operation he thinks, is too much neglected. By drawing off the urine in this manner the congestion is relieved, and the probability is that in a few hours an instrument can be passed through the urethra.

DR. COLLINS said that he had practised both methods, but chiefly relies upon bougies, and, after passing the large sizes, he has had complete success. He has used Gouley's catheters and filiform bougies, and has often been successful with them. In some cases he has performed internal urethrotomy. He fully agrees with Dr. Deaver in regard to the absolute necessity of relieving strictures of large calibre, but he is not prepared to say which of the proposed operations is the best. His plan is to begin with one method, and if that fails try others, and if he then fails, to aspirate.

DR. ROBERTS thought that there were one or two points that had not been thoroughly brought out in the discussion. The patients referred to by Dr. Morton and Dr. Hunt belong to the poorer class that comes to a general hospital for relief. These patients, if they secure a fairly-good stream of urine, are delighted, but such a result would not be sufficient for a man in the higher walks of life. It seemed to him that we should take the difference between these two classes of cases into consideration. He doubted whether Dr. Morton or Dr. Hunt followed this commoner class of cases sufficiently closely to say whether the strictures return and whether the necessity for the use of the bougie for several years is not a disadvantage.

The speaker said that he sees a comparatively small number of cases of stricture, but he almost always gets good results with gradual dilatation. He finds filiform bougies very useful, and has frequently succeeded in passing a filiform instrument after failing with a solid bougie. If, in a case of retention, he succeeds in introducing a filiform bougie, he is willing to leave the case temporarily, for there will be an escape of a certain amount of urine along the bougie which will relieve the distention of the bladder.

He would like to hear from Dr. Deaver whether, after the cutting method, it is necessary to continue dilatation for a long time.

DR. J. HENRY C. SIMES thought that the discussion was a little "mixed up" in reference to the "cure" of stricture. He does not believe in the cure of stricture. It is an anatomical impossibility to restore the urethra to its normal condition after a stricture has formed. There is, however, no doubt that we relieve the case decidedly; how the relief is obtained is immaterial to the patient. He thinks that the result depends largely upon the patient; if the subject makes no complaint we must consider him relieved. Therefore we find great differences. In highly-nervous patients the speaker has sometimes been obliged to resort to something more than dilatation. He has done internal urethrotomy in some cases, but has also been compelled to continue the dilatation. He has seen strictures return after both internal urethrotomy and after dilatation; therefore, he said, we do not cure the stricture. He begins the treatment with the method which, in his experience, offers the least risk—that is, dilatation—and continues it as long as necessary. If that relieves the

symptoms, he considers the case cured for the time being; if it does not give relief, he resorts to internal urethrotomy, and follows it by dilatation.

He considers filiform bougies of great service, and does not think that a steel instrument smaller than No. 10 or No. 8 French is a safe instrument to use in the pathologically-changed urethra. No. 6 or No. 4 is almost a cutting instrument, and in a diseased urethra there is great danger of making a false passage. With a filiform bougie there is very little danger, and he has succeeded in introducing one after failing with other instruments.

DR. DEAVER, in closing, said that he could not understand how an advanced surgeon at the present day could take the ground that had been taken by some of the Fellows in this discussion. In regard to evil results from internal urethrotomy, he has operated on about fifty cases, and has not seen the slightest complication. Dr. Otis reported at one time one thousand cases of internal urethrotomy without a death, and practically without a complication. The only complication that the speaker has seen is curvature of the penis from inflammatory deposit, which was entirely relieved by the absorption of the deposit.

He considers such instruments as Wakling's tubes relics of barbaric surgery. The instruments may split and bruise the urethra, causing much more serious damage than does the small incision made by the urethrotome. If surgeons would make urethroscopic examinations after dilatation they would find that it leaves conditions which could not be produced by the urethrotome. In one case, which he demonstrated to the class at the Philadelphia Hospital, the dilatation left a polypoid mass at the seat of stricture.

In order to be sure that a case is cured the urethra should be measured some time later. He then asked how many of the gentlemen had done this, to which Dr. Porter replied that he had done it often.

Dr. Deaver then said that when the *bougie à boulé* is used we cannot be sure of the results. Accurate results can be obtained only by the use of the urethrometer.

He uses filiform bougies if he cannot get the consent of the patient to do an external urethrotomy. He was glad to hear Dr. Morton say that in impermeable strictures he would resort to external urethrotomy. He does not feel at ease, as does Dr. Roberts, when he has passed a filiform bougie through a very tight stricture with the object of allowing it to remain, as it has a tendency to set up inflammation and ulceration of the walls of the urethra. As Dr. Roberts said, some patients are satisfied even if the result is not perfect, but the cases reported by the speaker occurred among the better class of patients—patients who are not satisfied until they are perfectly cured.

He is not in favor of the plan of trying for a long time to pass an instrument through the urethra. We would not follow a similar plan in strangulated hernia. The patient may have cystic kidneys, and he thinks that it is just as bad to prolong operative interference in retention of urine as it is in strangulated hernia. Aspiration had been referred to, but this is merely a temporary expedient, and the stricture will subsequently require treatment; it may be by internal or by external urethrotomy.

The great objection to gradual dilatation is that the instrument is passed into the bladder and bruises the sensitive prostate gland, and he believes that this is one of the most common causes of prostatorrhœa. He did not claim that after internal urethrotomy we may not have to pass an instrument, but four or five weeks is sufficiently long to use a bougie. He added that some strictures are never cured, but he is sure that many can be cured. The operation of dilatation is much more liable to be followed by contraction than is that of dilating internal urethrotomy, which makes only a slight incision. The lips of the incision are not allowed to come in apposition, and it heals by granulation, leaving a cicatrix, which can be discovered only by careful examination. After dilatation the scar is readily seen.

CORRESPONDENCE.

CHICAGO.

To the Editor of THE MEDICAL NEWS,

SIR: At a recent meeting of the Chicago Medico-Legal Society a resolution was adopted to the effect that public *séances* of hypnotism, mesmerism, and magnetism should be prohibited by law, and that hypnotism for medical purposes should be practised solely by duly-qualified medical men, and only in the presence of other medical men or undoubted friends of the patient operated upon. Drs. M. H. Lackersteen, Archibald Church, and J. C. Henry were appointed to present the resolution to the Legislature.

There is a rumor that diphtheria is epidemic in Chicago, but the facts at hand do not seem to substantiate the rumor. Reports from the Health Office show a decrease in the number of deaths from diphtheria as compared with the corresponding period of last year. Added to this are the statements made by many prominent physicians, who, in nearly every case, declare that there is no cause for alarm over the spread of diphtheria or other zymotic diseases. In November, 1890, there were 288 deaths from zymotic diseases, of which number 78 were due to diphtheria, 46 to croup, 67 to typhoid fever, and 13 to scarlet fever. In November, 1889, there were 355 deaths from zymotic diseases. Of these, 125 were from diphtheria, 62 from croup, 68 from typhoid fever, and 11 from scarlet fever. The total death-rate for the month of November, 1889, was 1504, and for November, 1890, 1480, showing a decrease in the general mortality as well as in that of zymotic diseases.

The work of the Woman's Hospital is steadily increasing. Notwithstanding the heavy blow dealt the institution by the death of the president of the medical staff, Dr. William H. Byford, the number of patients treated was greater than during any previous year. The medical department has a capacity of only 43 beds. Not less than 22 have been occupied at any time, and often 40 are filled. The whole number of days' service rendered by the hospital during the year was 11,315, of which 36 per cent. was charitable. The total receipts for the year were $18,416.19; disbursements, $18,385.83.

Dr. D. Mills Tucker, who had been a practising physician in this city for thirty-five years, died at his home on December 10th. He was exposed to cold

while attending a patient, developed acute pneumonia, and died in a few hours. He was born in Worcester County, Mass., in 1819, and was graduated from the Medical Department of Harvard University in 1852 He came to Chicago in 1856, and began to practise when the city was little more than a straggling village. He was one of the first physicians to interest himself in the cure of inebriates, and was medical adviser of the Washingtonian Home during the early days of that institution.

Dr. Thomas A. Clark, while treating a patient in his office, December 8th, was suddenly stricken with apoplexy, and died a few minutes later. He was born on a farm near Louisville in 1825, and was graduated from the Kentucky School of Medicine in 1852. From Louisville he went to Jefferson, Ind., and practised there until 1855, when he came to Chicago. For thirty years he was eminently successful as a physician and surgeon, his specialty being obstetrics.

At a meeting of the Public Service Committee, Dr. J. R. Brandt offered a resolution to the effect that no physician should be allowed to act at county institutions as attendant surgeon or physician who has not previously had a practical experience of five years, or who has not served the full term as an interne at the county hospital. The resolution was referred. Dr. Brandt wanted the office of county physician abolished, as he thought the work could be done for $350 per annum. He thought the office was a sinecure, as the coroner had a physician who made all the post-mortem examinations.

NEWS ITEMS.

The Mattison Prize.—With the object of advancing scientific study and settling a mooted question, Dr. J. C. Mattison, of Brooklyn, offers a prize of $400 for the best paper on "Opium Addiction as Related to Renal Disease," based upon these queries:

"Will the habitual use of opium, in any form, produce organic renal disease?

"If so, what lesion is most likely to occur?

"What is the rationale?"

The contest is to be open for two years from December 1, 1890, to either sex, and any school or language.

The prize paper is to belong to the American Association for the Cure of Inebriety, and will be published in the *New York Medical Journal, Brooklyn Medical Journal*, and *Journal of Inebriety*.

Other papers presented are to be published in some leading medical journal, as their authors may select.

All papers are to be in possession of the Chairman of Award Committee on or before January 1, 1893.

The Committee of Award will consist of Dr. Alfred L. Loomis, President of the New York Academy of Medicine, Chairman; Drs. H. F. Formad, Philadelphia; Ezra H. Wilson, Brooklyn; George F. Shrady, and Joseph H. Raymond, editor of the *Brooklyn Medical Journal*.

The Swatow Mission Hospital.—The largest of the mission hospitals in China is that of Swatow. The number of in-patients treated during the past year was 2679. There were 3151 out-patients, a relatively small number. The expenses were $2275. More than 250 cases of leprosy applied for treatment, to which only palliative treatment could be given. Surgical measures were required in about twenty per cent. of all cases.

Corrigendum.

THE TREATMENT OF FAILING CIRCULATION.

In the article on the "Treatment of Failing Circulation," by Dr. C. S. Bradfute (THE MEDICAL NEWS, January 3, 1891), line 18 from the bottom of the second column, page 16, should read "in the course of *typhoid* fever."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 13 TO JANUARY 19, 1891.

By direction of the Secretary of War, HENRY D. SNYDER, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Reno, Oklahoma Territory, and will report in person to the commanding officer Camp Guthrie, Oklahoma Territory, for duty at that station, relieving John L. Phillips, Captain and Assistant Surgeon. Captain Phillips, on being relieved, will report in person to the commanding officer Fort Reno, Oklahoma Territory, for duty at that station.—Par. 16, *S. O. 11, A. G. O., Washington, D. C.*, January 14, 1891.

PROMOTIONS.

To be Assistant Surgeon, with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874:

HARRIS, HENRY S. T., *Assistant Surgeon*, January 5, 1891.

WOOD, LEONARD, *Assistant Surgeon*, January 5, 1891.—*A. G. O., Washington. D. C.*, January 12, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 17, 1891.

HORD, W. T., *Medical Director.*—Ordered, as President of the Medical Board, to relieve Medical Director J. Y Taylor.

DEAN, R. C., *Medical Director.*—Detached from Hospital, Chelsea, and ordered to the Medical Board, Washington, D. C.

TAYLOR, J. Y., *Medical Director.*—To be placed on the Retired List, January 22, 1891.

RUSH, W. H., *Passed Assistant Surgeon.*—Orders to the U. S. S. "Newark" are revoked.

ASHBRIDGE, RICHARD, *Passed Assistant Surgeon.*—Orders to the U. S. S. "Saratoga" revoked, and to await orders.

CABELL, A. G., *Passed Assistant Surgeon.*—Detached from Iron Clads and ordered to the U. S. S. "Newark."

LUMSDEN, G. P., *Passed Assistant Surgeon.*—Ordered to the Iron Clads at Richmond, Va.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

AN EFFORT TO OBTAIN A PERFECT SUBSTITUTE FOR HUMAN MILK.

Based on Chemical and Clinical Studies.[1]

BY BARTON COOKE HIRST, M.D.,

PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA.

THERE is no more important subject in obstetric practice to-day than the artificial alimentation of infants. Indeed, there are few questions in the whole realm of medicine that transcend it in interest. In this city, in the past three years, 1887 to 1889 inclusive, there have been, in round numbers, 75,000 living children born; during the same period 16,000 children have died before completing their first year—a death-rate of something over 21 per cent.[2] In other words, one-fifth of the children born alive in Philadelphia die before they are one year old—a stupendous mortality, but other large cities show a still worse record. The chief cause of the high death-rate is undoubtedly to be found in diseases of the digestive tract, which come from bad feeding. This does not appear so plainly as it should in the mortality records of the city. One needs little experience to learn that fatal cases of intestinal infection in young children are reported in the death-certificates under all sorts of misleading names, such as, marasmus, cerebritis, convulsions, inanition, debility, etc. But the fact remains indisputable, that if digestive disturbances could be eliminated from the fatal disorders of infancy, a vast army of children would be saved to their parents, and a large number of citizens be added to the State, with a gain, from a humanitarian point of view, that is incalculable, and from a purely material point of view that could be reckoned in enormous sums of money.

By the march of modern investigation such a result, in great part at least, has become a possibility. It needs only a wide dissemination among the laity and the medical profession of knowledge now in the possession of, comparatively, a few, greatly to reduce the mortality of early infancy. That a large number of physicians need instruction on this subject cannot be denied. Last summer I saw two striking illustrations of the fact. In one case, a child of three months was fed, by order of its physician, on a mixture of one teaspoonful of condensed milk to sixty of water. It had come to the verge of starvation on its diet. In the other case a baby eight weeks old had been ordered by the family physician, in the heat of summer, six ounces of unsterilized milk with Mellin's food every two hours. The child died of cholera infantum. Both these physicians were in active general practice, and I dare say that the children who had fallen victims to their ideas on infant-feeding could be counted in large numbers. And these are but single examples of a large class.

The disadvantages attaching to the use of cow's milk—the only practicable substitute for human milk—in the feeding of infants may be summed up as follows:

Cow's milk differs in the proportions of its chemical constituents from human milk.

Cow's milk, as ordinarily obtained, especially in summer, swarms with many varieties of microbes, and is contaminated, perhaps, with the products of their activity. It is, moreover, acid. Human milk, on the contrary, is drawn from the breast and received into the infant's stomach sterile. It is alkaline.

Cow's milk can be administered in almost unlimited quantities and at any interval. Human milk is supplied by the mother's breast, in quantities and at intervals suited to the demands of her infant's economy.

Each of these factors could defeat an attempt to nourish an infant on cow's milk alone; but, operating together, as has usually been the case, it is little wonder that artificial infant-feeding in the past was one long record of failures. To the theoretical student of the subject at present it might seem that every difficulty has been removed. With the knowledge obtained a comparative chemical study of cow's milk and human milk, notably by Arthur V. Meigs's work, one can construct, with cow's milk as a basis, a correct chemical imitation of human milk.[1] By the labors of

[1] Read before the College of Physicians of Philadelphia, January 7, 1891.

[2] In exact number as follows:

1887—23,140 living births, 5296 deaths under one year.
1888—25,163 " " 4977 " " " "
1889—26,244 " " 5268 " " " "

[1] The future has much to teach us in the comparative chemistry of proteids in milk. In Meigs's formula, that which is designated by the loose and incorrect term "casein," but which should be known as caseinogen, is reduced to the proportion of this substance usually found in human milk. But the information which physiological chemists must, before long, furnish practical workers in

Jeffries, Soxhlet, and others, the chemical imitation of human milk can be administered in a sterile condition. And by the investigations of Snitkin, L. Emmett Holt, and others, we have definite and correct ideas in regard to the quantity of food to be given at each feeding, the interval that should elapse between the feedings, and the rate of increase in quantity required from month to month. With such knowledge, which is but recently available, it would seem possible to construct an artificial infant-food equal in all respects to the mother's milk. But the confidence inspired by this idea would sooner or later be rudely shaken in practice.

For some time my own experience led me to hope that we had at last secured the ideal infant's food. My system, based on Meigs's and Rotch's work, with sterilization and adjustment of quantity and interval to the infant's age, is expressed upon the card which I had printed for distribution among those of my patients who required it.

CARD No. 1.

1. Have ten bottles prepared clean every morning.
2. Put in each of them, through a clean glass funnel:

Cream	dr. iv.
Milk	dr. ij.
Water	oz. j.
Milk sugar	gr. l.

[One measure].

3. Stopper the mouth of each bottle with dry baked cotton, and sterilize for twenty minutes.
4. Set aside to cool.
5. Add lime-water, dr. ij, to each bottle before use.
6. Apply a plain rubber nipple to the bottle.
7. Warm to blood-heat in warming-cup.

For a time, I say, this plan yielded the most gratifying results. One child, in particular, I recollect. It weighed ten pounds at birth. The mother had fever for about three weeks after delivery, from an infected endometrium, during which time the child was kept upon the bottle. After a while the mother's milk gradually increased in quantity, so that at the end of the first month the infant was fed at the breast, with the exception of a bottle morning and evening. A week later the child was seized with acute dyspeptic symptoms and diarrhœa. I attributed the trouble to the artificial feeding, which I ordered discontinued; but the child grew worse. The mother's milk was then analyzed, and found to contain but 0.8 per cent. of fat, with 1.17 per cent. of casein. The artificial feeding was resumed, and the little patient at once picked up, gaining from that time an average of two pounds a month up to the last report that I received at the sixth month. But soon there came a succession of failures. The most conspicuous was in the case of a healthy infant born at term of exceptionally healthy and well-developed parents. From the first it was necessary to give this child the bottle. It did not thrive. On the contrary, by the third week it had become obstinately constipated and was visibly wasting away. From my own observation, and from what I had heard of others' experience, I had already learned to suspect that sterilization is the disturbing factor in the effort to produce an ideal infant-food. Consequently, the infant was taken from the mixture described on the card, and put upon condensed milk (1 part), water (12 parts), and cream (1 drachm to an ounce of the mixture). The change in the child's condition was rapid and striking, and at the third month, when I saw it last, it had become in weight, color, and appearance as fine a specimen as one would wish to see.

About this time I assumed charge of the children's wards in the Philadelphia Hospital, with the determination to learn what change sterilization caused in the chemical imitation of human milk and to find a way, if possible, of obviating the alteration. On first thought it seemed that the trouble lay in a disturbance by heat of the chemical constitution of the mixture. It had been asserted that, in boiling, milk loses 3 per cent. of gases (CO_2,N,O) and that 20 per cent. of the albuminoids is coagulated in a thick scum upon the surface (Townsend), and I thought that sterilization might also be productive of a somewhat similar chemical change. But on further consideration, and especially after reading two very interesting articles by Béchamp,[1] it seemed more reasonable to suppose that the unfavorable action of heat upon milk consists in a coagulation of the albumin, especially that around the fat globules, making them, already tougher than in human milk, still more tough and difficult of disintegration in the process of digestion. The question, however, could only be settled by a careful chemical study, and this Dr. Hiestand very kindly undertook for me. The interesting report of the work, just concluded, follows in full:

NOTES ON THE EFFECT OF STERILIZATION UPON MILK.

"To determine what changes occur in milk as a result of sterilization, analyses were made of numerous samples of normal cow's milk and of the feeding mixture used by Dr. Hirst.[2] The results of these experiments showed no change in the total solids of

regard to the relative proportions of lact-albumin in the two milks, and as to the quantity of whey-proteid which appears on the formation of the curd or casein, may, and I think will, necessitate a change in the formula for constructing a chemical imitation of human milk. In this connection see the interesting article by Halliburton, Journal of Physiology, xi. 6, November, 1890.

[1] Bulletin de l'Académie, 3d série, t. xx. p. 718 and Ibid., t. xxiv. p. 214. Béchamp shows that the fat globules in milk are surrounded by a pellicle of albumin; that in human milk this pellicle is more delicate, and more distensible, than in cow's milk.

[2] See card No. 1.

any sample examined before and after sterilization. The amount of albuminoids, fat, sugar, and salts in a given sample of normal milk, or of the feeding mixture referred to, may be recovered after sterilization without loss.

"Subsequent experiments show, however, that the organic constituents do undergo certain important alterations in condition which bear upon the question of assimilation. Observations were directed mainly toward the condition of the albuminoids, fat, and sugar, with the following results:

"I. ALBUMINOIDS.—A. Sterilized and unsterilized portions of a milk-sample were saturated with magnesium sulphate, the precipitated casein separated by filtration, and the albumin estimated in the filtrate. The unsterilized sample yielded 0.33 per cent. of albumin; the sterilized only 0.013 per cent., about 96 per cent. of the albumin, in the latter case, having been coagulated by heat and carried down with the casein.

"B. The percentage of casein in the foregoing sample of milk was 3.27, as shown by a calculation based upon the total nitrogen in the milk. On account of the difficulty of separating the coagulated albumin from the precipitated casein, no observations were made on the condition of the casein before and after sterilization.

"A number of experiments to determine the changes in casein after boiling have been undertaken by various observers; but, thus far, the results have been too conflicting to be reliable. Soldner (quoted in the report of the United States Department of Agriculture, 1890) gives some notes made by Hammersten to the effect that the casein in milk is changed by a temperature of 212° F. The evidence seems to be that the calcium in milk is in some way combined with the casein, and that this combination is modified by a boiling temperature. The exact nature of this change is not well understood. It seems probable, however, that an alkaline calcium compound is formed, which may overcome the natural acidity of the milk. This would explain the altered behavior of rennet in sterilized milk. The experiments incident to his report corroborate those of previous observers and show that sterilized milk coagulates with rennet much less promptly than unsterilized milk. The addition of a small quantity of acid is found to restore to the milk its coagulability by rennet, probably by overcoming the alkalinity produced by boiling.

"II. FAT.—After sterilization the milk was covered with what appeared to be a thin layer of butter-fat. To ascertain whether any fat-globules were freed from their albuminous envelopes, a portion of sterilized milk was rotated in a centrifugal machine for several minutes, along with an equal quantity of unsterilized milk in a separate flask. It was observed that a noticeable proportion of free butter-fat was obtained from the sterilized sample, while the unsterilized sample yielded only the usual layer of cream. This and the following experiments show, however, that only a small proportion of the fat is freed, and that, on the other hand, the globules not liberated have their envelopes so altered by heat as to lessen their tendency to coalesce:

"*a*. Sterilized and unsterilized portions of milk were churned, and a note made of the time required to form appreciable amounts of butter. The unsterilized portion yielded butter in one-third less time than the sterilized portion.

"*b*. Sterilized and unsterilized milk shaken up with equal parts of ether and petroleum spirit, and allowed to stand for twenty-four hours, showed, by microscopical examination, no obvious variation in the size or condition of the fat-globules.

"III. SUGAR.—Examinations of milk before and after sterilization were made both by polarimetric and reduction methods. It was found that the whey of the unsterilized sample had a dextro-rotatory power appreciably greater than that of the sterilized sample. The actual figures for the amount of sugar solution taken were, for the sterilized sample, 3.47, and for the unsterilized sample, 3.87. These figures were confirmed by duplicate analyses. The comparative reducing power of both samples on Fehling's solution was, however, but little affected, the slight differences noted being within the limits of experimental error. The exact nature of the change indicated by the polariscope has not been determined.

"The following is an epitome of the ascertained results of sterilization:

"1. Albumin coagulated.

"2. Casein less readily precipitated by rennet than in normal milk. Acid corrects this condition.

3. "Fat is freed to a slight extent; fat not freed has a lessened tendency to coalesce.

"4. Sugar undergoes some change, as shown by its lessened dextro-rotatory power.

"The considerations suggested by a knowledge of the foregoing facts are:

"I. The coagulation of milk-albumin by sterilization may render the milk more difficult of digestion.

"II. Sterilization interferes with the coagulability of milk by rennet, and presumably, therefore, with its digestibility by the gastric juice. [This scarcely agrees with our present ideas.—B. C. H.]

"III. Free fat, as found in sterilized milk, is probably not readily assimilated in infant-food. The fat not free, being enclosed in a less-easily destructible envelope, is probably slow of digestion.

"For valuable assistance in conducting these experiments I am greatly indebted to Mr. William Beam. My thanks are also due to Dr. Henry

Leffmann for the use of his laboratory, where the experiments were made.

"ELEANOR MOORE HIESTAND, M.D.,
" Demonstrator of Chemistry in the Woman's Medical College of Pennsylvania "
" PHILADELPHIA, December, 1890 "

Being sure that the chemical study would bear out the theory in regard to the effect of heat upon the fat-globules and albumin, I adjusted the clinical work to this idea as soon as the chemical investigation had been fairly started. The only way to obviate the action of heat lay obviously in a partial predigestion of the milk and cream; and the only agent at our command to accomplish this result is pancreatin.

The chemical study takes no account of predigested food, as Dr. Hiestand and myself were working independently at the same time, and were ignorant of each other's work till the whole was completed. One of the methods, described in the report, of comparing sterilized with unsterilized milk suggested to me the following idea: If predigestion with pancreatin really affects the fat-globule and makes it easier to free the fat, this action should be demonstrable by the different effects of churning upon predigested milk and cream, upon sterilized predigested milk and cream, and upon sterilized milk and cream. In the first, three minutes' churning of half a tumbler of the mixture produced enough butter more than to fill a teaspoon. The churn used is a small tin affair sold in housefurnishing shops for making whipped cream, which it takes ordinarily about four minutes to do. In the second, less than four minutes' churning of one and one-half ounces produced a good-sized lump of butter. In the third, it took about twelve minutes to form butter at all, and there was not as much by that time as had been produced by four minutes' churning of the predigested sterilized specimen.

There remains to be supplied one more chemical link in the chain of evidence. The stools of children fed upon sterilized and predigested sterilized milk should show a difference in fat contents. We already know that a diet of boiled milk is accompanied by an excess of unassimilated fat in the stools.[1] I should expect to find less unassimilated fat in the stools of infants fed upon predigested sterilized milk than in those fed upon simple sterilized milk. I hope to have this point investigated in the near future, or to learn the truth about it from the work of others.

Still retaining the chemical proportions suggested by Arthur V. Meigs (with the single exception of sugar), and observing the rules for quantity and interval suggested by Snitkin and Holt, the following card was drawn up:

[1] Vasilieff: Thèse inaugu., St. Petersburg, 1889.

CARD NO. 2.

[Front.]

1. Have ten nursing-bottles prepared clean every morning.
2. Take

Cream	5 ozs.
Milk	2½ ozs.

3. Put in skillet; add pancreatin powder; heat over alcohol flame for six minutes; stir and sip constantly; *do not overheat.*
4. Of this mixture, put in each bottle 6 drs. (to make 2-oz. bottle). Use funnel.
5. Add to each bottle 10 drs. sugar solution.
6. Stopper the mouth of each bottle with dry, baked cotton, and sterilize for twenty minutes.
7. Set aside to cool.
8. Before use, put bottle in warming-cup; apply nipple immediately before giving it to infant.

Make sugar solution by dissolving 1 oz. sugar of milk (1 powder) in a pint of warm water.

[Reverse.]

Age.	Interval.	Number of feedings in 24 hours.	Amount of food at each feeding.	Total amount in 24 hours
1st week . . .	2 hours.	10	1 oz.	10 ozs.
2d to 4th week .	2 hours.	9	1½ oz.	13½ ozs.
2d to 3d month	3 hours.	6	3 ozs.	18 ozs.
3d to 4th month	3 hours.	6	4 ozs.	24 ozs.
4th to 5th month	3 hours	6	4–4½ ozs.	24–27 ozs.
6th month . .	3 hours.	6	5 ozs.	30 ozs.
8th month . .	3 hours.	6	6 ozs.	36 ozs.
10th month . .	3 hours.	5	8 ozs.	40 ozs.

The pancreatin powder, for the quantity indicated on the card, consists of

℞.—Pancreatin	2½ grains.
Bicarbonate of sodium . .	5 "

The sodium salt furnishes the alkalinity desired, so that lime-water may be dispensed with.

The objection urged against the partial predigestion of an infant's food, that, by so doing, one deprives the digestive jucies of their natural work, and thereby incurs the risk of atrophy of the digestive glands, while at first sight forcible, is in reality weak. If, by this method, the food-mixture is reduced to a condition in which there is about as much for the child's digestive powers to do as though it were fed on human milk there is no danger of abrogating any digestive function.

The sugar of milk is prepared in less amounts than would be called for in an exact chemical imitation of human milk. I am not sure that I will not still further reduce the proportion. Although sugar from cow's and human milk is chemically identical, physiologically it cannot be so, for I have often remarked the diuretic properties of lactose from cow's milk when given to an infant, and I have verified the discovery made by others that the

lactose of cow's milk can produce a very marked glycosuria in bottle-fed babies.

All the infants in the Philadelphia Hospital during September, October, November, and December that were deprived of their natural nutriment, to the number of twenty-one, were fed after this plan. They were weighed daily and their weight entered upon the weight-sheets which I had printed in the hospital. At first a daily record of their stools was kept, but as none of them became constipated this was not continued. In this connection I must express my thanks to the nurses of the hospital for the faithful manner in which they performed an arduous task.

The loss in these four cases was not due to the feeding. In two it was caused by disease, in two others, I think, by the unfavorable hygienic condition in the hospital. The five remaining children died, and naturally lost considerably in the course of their fatal illness. Two of these children were syphilitic, with extensive skin eruptions, and in one of them severe purulent ophthalmia. One died of capillary bronchitis, the other of very severe entero-colitis. This case was especially interesting, for in spite of the care to sterilize its food, the same symptoms were developed with the same fatal result as though the child had received the worst-infected milk procurable. I believe that in

CHILDREN'S WEIGHT-SHEET.

These weights are given by weeks, and in pounds and ounces, thus, 7.2 = 7 lbs. 2 ozs

Lenmon Collins,	3 months.	7 4														

It will be seen by the tables that four children were under observation less than a week. They will not be considered. The remaining seventeen infants were of all ages under eight months, some of them very young. Of this number eight gained in weight, nine lost. Of the latter number four lost only a slight amount.

CASE I.—James Ryan, two months old, lost 4½ ounces in four and one-half weeks. In the first three weeks in the hospital he gained 4 ounces, but in the last twelve days before leaving, during which time he had bronchitis, he lost 8½ ounces.

CASE II.—George Carpenter, three months old, lost 4 ounces in one week and a half.

CASE III.—J. Lappan, seven and one-half months old, lost 5 ounces in two weeks.

CASE IV.—Nellie Johnson, one month old, lost 1 ounce in six weeks. This child gained 9 ounces in the first three weeks, but acquired what was at first thought to be pneumonia, but is now believed to be tuberculosis, with consolidation of the upper part of one lung. During the three weeks of her disease she has lost 10 ounces.

children of miserable development, as in this case, the food, though given sterile, decomposes in the intestinal tract, for it is only reasonable to suppose that, when all other vital functions are performed imperfectly, the digestive juices are insufficient not only to digest the food, but even to keep it from rapid putrefaction. The third infant of this series, Gilbert Burney, died of tuberculosis. The whole upper lobe of one lung was consolidated. Of the other two children, one showed a scar of old ulceration in a Peyer's patch, and several fresh ulcers with congestion of the large intestine and disease of a few solitary follicles. This was undoubtedly a case of entero-colitis from food-infection, to be explained, I think, as in one of the syphilitic children. The second infant presented really nothing in the post-mortem examination to account for the death. There was no appreciable entero-colitis, though the mesenteric glands were slightly enlarged. The body was intensely anæmic and very thin. The child appeared simply to waste away.

Of the children who gained in weight, I would

direct attention particularly to one, Elizabeth Bartling, aged four months, who gained 4 pounds and 8 ounces in three months and a half, increasing from 8 pounds 6 ounces, to 12 pounds 14 ounces. It is a significant fact that this infant was not in the foundling ward at all, but in a much larger, better aired room, and in charge of her mother. She was one of twins, one of which was kept on the breast, the other on the bottle. The bottle-fed baby has gained faster than its sister.

I am conscious of much that is imperfect in this clinical study. My material was numerically small. The condition of the infants, many of them picked up on vacant lots, others with parents in the last stages of phthisis, or in the insane department, was in the main very bad, and the environment in the foundling ward of a large hospital is, at the best, unsatisfactory. On one point, however, I am satisfied, namely, that the work of the nurses and resident physicians was earnestly and carefully done. It is on work of this character alone—careful attention to details of feeding and of observation—that a true system of artificial alimentation can be founded. It is a tedious and a troublesome task, but it will amply repay the hardest work—for the discovery of an ideal infant's food that gives as good results as mother's milk will do as much to save life and prevent disease as Jenner's discovery, or that of Koch, even if it proves all that is claimed for it.

In conclusion, a few words as to the practical execution of the directions on card No. 2 in private practice—small matters, apparently, but they may mean the difference between failure and success. First, in regard to the sterilization. This is undoubtedly a burden to the child's attendant, which it should be the physician's care to make as light as possible. The best sterilizer, in my opinion, for convenience and efficiency, is the Arnold's steam cooker. It is easy, however, to devise some arrangement, in a family too poor to buy a sterilizer, that will answer the purpose. As to the bottles, they should be, according to the card, "prepared clean every morning." I have lately seen somewhere the advice to boil the nursing bottles for an hour every day. It reminded me of the excesses committed in the name of antiseptic obstetrics at a time when, in certain hospitals, the child emerged from the vagina under a carbolized spray. It is only necessary to clean the bottles with a strong soda solution and bottle-brush, and then rinse them out well in hot water. They and their contents are made sterile or chemically clean in the sterilizer at the same time. The bottles should be of a form that permits of easy cleansing; as far as possible from the shapes that are at present most in use. Rotch's bottles are the best in this respect upon the market, but their shape is awkward, and their price precludes the possibility of their general use. A drug firm is at present making for me a feeding-bottle which will have a wide mouth, almost no shoulder, no sharp angles, and shall be of moderate price.

Very careful directions must be given in regard to the predigestion of the milk and cream. The time—six minutes—should be indicated by an open watch before the person who prepares the food; it should never be guesswork. The direction should be given never to let the preparation get hotter than one usually drinks the morning coffee. By the end of six minutes the mixture begins to have a distinctly bitter taste. It always takes a minute or two to distribute the milk and cream among the nursing-bottles; this should be done quickly and everything should be in readiness to begin the sterilization at once, for should the mixture in the skillet remain hot for ten minutes in all, it might be so bitter as to be unfit for use. The steam heat, of course, stops the digestion at once.

It is well worth the trouble, in private practice, to conduct properly the whole procedure once before the child's caretakers.

Finally, the nurse or mother must be told to hold the child in the lap while it is fed and to make it consume some time, about ten minutes, in taking the bottle. This is a matter usually understood, but in some cases it needs the physician's express attention. In all cases it is essential to success. I was much impressed with the truth of a remark made by a lady, once a trained nurse, now the wife of a distinguished man and herself a mother, who said on a visit to the foundling ward recently, "It is not so much science that these babies need as a mother's coddling."

ACUTE DELIRIUM—PROBABLY AN INFECTIOUS PROCESS.[1]

BY JAMES HENDRIE LLOYD, M.D.,
PHYSICIAN TO THE NERVOUS AND INSANE DEPARTMENT OF THE PHILADELPHIA HOSPITAL AND TO THE HOME FOR CRIPPLED CHILDREN, PHILADELPHIA.

UNDER a multiplicity of terms a form of serious brain-affection, characterized especially by delirium and rapid exhaustion, has been described by various authors. Some of these terms are typhomania, or Bell's disease, delirium grave, acute delirious mania, and *délire aigu*, by French writers. The older writers were apt to speak of the disease as "paraphrosyne," or phrenitis, thus indicating their conception of the morbid process underlying it. Some modern authors, with their passion for clinical differentiation, have probably included kindred cases of a mild type, under such titles as stuporous insanity and confusional insanity. The type of the

[1] Read before the Philadelphia Neurological Society, November, 1890.

disease is well exhibited in the delirium which attends typhoid fever and other infectious diseases, and the morbid process is probably not dissimilar. This disease, or, properly, class of diseases, has been also described under special names, according to its causation, thus, puerperal mania, post-febrile insanity, post-operative insanity, septicæmia, exhaustion from overwork, sewer-gas and other poisoning, have all included this acute delirious condition. A few physicians fall back upon the word "meningitis," to explain the disease, and it may be a question whether a few of the cases have not been called delirium tremens.

Some authors include in delirium grave only rapidly-fatal cases, while others include less severe, long-continued, and curable cases. The mere clinical distinctions are too often arbitrary, and are entirely uninstructive as to the exact causation. I have seen one case which proved fatal in less than three days, while another extended over several weeks, and recovered. In both of these cases the condition was a typical delirium, with dried secretions, brown tongue, rapid pulse, variable temperature, and exhaustion, with emaciation. There is no sufficient reason to place these cases in separate classes, with distinctive names, simply because one died and the other lived. So, again, the type of delirium may vary, as may also its severity. One case may be of a low, muttering form, tending to stupor, dementia, and death, as has been reported after some of the exanthematous diseases, such as scarlatina and smallpox; another may exhibit rather a confusion of intellect with active hallucinations, and persist for weeks, with final recovery, as is frequently seen after childbirth. This fact does not seem to me a sufficient reason for a classification which shall be final, especially as the active causation in each case is practically as yet unknown.

The symptomatology of these cases varies, but presents a sufficient number of resemblances to constitute a simple broad class. The mental symptom is usually wandering delirium. In milder cases the attention can be momentarily arrested, and a question or two answered; but the mind soon lapses into more or less complete object-unconsciousness. Subject-consciousness is much confused, and is apt to be dominated by visual and aural hallucinations. From this stage all grades of delirium to complete stupor and coma can be observed. The physical state accompanying the delirium is apt to be that which is spoken of generally as "typhoid," and grows more marked the longer the acute stage lasts. The tongue becomes dry and brown, and sordes form. The breath is offensive. The pulse is rapid and compressible. There are muscular unsteadiness, tremor, and incoördination. The temperature occasionally rises, but not in all cases, and in my experience pursues no regular course. The gastro-intestinal tract in my cases was not involved, except that there were aversion to food and retention of fæces. In puerperal cases of this type there may be foul lochia and pain on pressure over the uterus, but these symptoms are not present in every case. In two well-marked cases of delirium following childbirth I could discover no focus of septic infection, although I searched for it. Still, I believe they were the results of infection. In one puerperal case seen in the Pennsylvania Hospital for the Insane, under Dr. Chapin's care, the patient's active delirium came on within a month after confinement, and was marked by anæmia, emaciation, and a brown dry tongue. She had had at first fleeting, delusive ideas, and rapidly became immodest, restless, and troublesome in every way. She talked incoherently, but later had a fixed, staring gaze, with dilated pupils, and would not respond to questions. There was no abdominal soreness and no fever. The blood-count showed that the corpuscles were reduced twenty per cent. It is usual to call such cases "puerperal insanity," yet their likeness to acute delirium, especially when they are severe, is too great to be ignored. Such cases sometimes run a very rapid "typhoid" course, and die, but in the main the prognosis in puerperal cases, if taken in time, is good.

In some of the cases, called post-febrile, such as are seen after scarlatina, smallpox, and typhoid fever, the early stage of the acute delirium is coincident with the acme of the infectious process. The mental condition at first is looked upon as merely the delirious reaction so commonly seen in the exanthemata, and is no doubt identical with that reaction; but as the specific disease subsides it is found that the brain-cells have not recovered from the toxæmia, and a psychosis results which may pursue a variable course, either as confusional insanity, insanity of fixed delusions, or, rarely, dementia. These cases are of special interest, because no one doubts that they are due to infection; hence, in them the action on the convolutions of specific infectious products, probably ptomaïnes, may be observed, and important hints and analogies supplied for the understanding of similar cases in which infection can only be surmised, and not demonstrated.

In the fatal case which Dr. Tull has reported (see page 127), and which I saw with him in consultation, the onset was very sudden and the course very rapid. In this case there was no known source of infection. We could exclude with reason alcohol, syphilis, uræmia, lead, and probably all the known zymotic poisons:

The patient had worked in a district which possibly was malarious. He was seized on a Saturday,

at midnight, and died on the following Tuesday morning, living less than sixty hours after the onset. He was an unusually robust man, less than forty years old, one whom it was not easy to kill. He was at first acutely maniacal, with what seemed slight hysteroidal symptoms, and his attention was held with difficulty and but for a moment. There was great motor disorder, so that he had literally to be held in bed. He struggled, resisted, spoke not a word, had stareing eyes, refused food, and seemed at times rather emotional and histrionic. His pulse at first was strong and good. His temperature varied, without regularity, and once rose to 103°. It was sometimes normal. His urine was not albuminous. He sank rapidly, as if under the influence of some baleful intoxicant, became comatose, and died. The autopsy revealed to the naked eye nothing but white streaks in the perivascular sheaths, which probably indicated the first attempts of nature to meet an invading irritant poison.

The diagnosis of some of these cases is extremely perplexing:

In a case which I saw with Dr. Gittings, in West Philadelphia, the patient, a man aged about forty-three years, lay for more than two weeks in a stuporous delirium. He was aroused with difficulty. His tongue was dry, brown, and hard, and his pulse feeble. There were absolutely no other symptoms to guide in forming a diagnosis. His temperature seldom, if ever, rose above normal. His urine was frequently examined, both chemically and under the microscope, with negative results. Alcohol and lead were not factors in the case. Syphilis was excluded as well as it usually can be, and the post-mortem lesions did not indicate this poison. The general appearance of the patient was somewhat like that of a man profoundly ill with typhoid fever, but the afebrile temperature, the absence of abdominal symptoms and eruption, negatived such a diagnosis. There was no history or appearance of trauma. An examination of the eye-grounds by Dr. de Schweinitz gave no results. At the autopsy the brain was removed before the great vessels in the thorax were cut—an important precaution. There was undoubtedly a great deal of blood in the brain, but a careful inspection of the vessels, membranes, and convolutions revealed nothing which could in any way explain such a grave disease. The longitudinal sinus contained a long, slender thrombus, which, however, did not occlude the calibre of that canal.

In a case under my care, in the Philadelphia Hospital, a protracted delirious state came on in a patient who had been for a year in a simple maniacal exaltation. I do not, of course, call it a case of acute delirium in the sense in which that term is usually employed. It was rather a delirium engrafted upon a mania. The case had all the usual accompaniments: altered secretions, rapid pulse, muttering incoherence, etc. The interesting fact is that *after* this delirium had been established for some time the patient had a diffuse cellulitis of the leg, erysipelatous in appearance. There was evidence here of some infection, but of what character I could not determine.

The symptoms of meningitis, or meningeal irritation, are seen in some of these acutely delirious cases. The following interesting case was admitted into the Pennsylvania Hospital for the Insane, where I examined the patient and signed the certificate. I am indebted to Dr. Chapin for notes of the case:

The patient was a woman, aged twenty-one years, who was reported to have had a "malarial attack" two months before admission. This illness left her in an impaired mental condition, marked by agitation, mental confusion, insomnia, and emotional disturbance. She rapidly grew worse, and was admitted to the hospital with a diagnosis of acute delirious mania. When I saw her she was in a typical delirious state. She was entirely incoherent and inattentive, muttering, and expressing what seemed to be fragmentary, delusive ideas. She evidently had hallucinations. The prevailing tone was apprehension and distress. She was restless, and was kept in bed with difficulty. Her tongue was coated, bowels constipated, pulse 105, and temperature 99⅘°. The pupils were dilated. A very marked symptom was the muscular spasticity, with convulsive movements in the hands and arms, and much exaggerated patellar reflexes. Her urine was examined in the hospital, and showed neither albumin nor casts. During the last week of life her temperature rose steadily day by day, until just before her death, when it was 104⅘°. Her skin was hot and oily. The loss of object-consciousness in this case was almost complete. An autopsy was refused.

It is notable in this case that hyperpyrexia was present, as well as a general spastic state of the muscles approaching a convulsive condition. The exact nature of the primary infection was apparently not made out It was called "malaria," but this term is so loosely used in the profession that often little meaning can be attached to it.

In the brief review here presented of these cases it has not been my aim to form any theory of causation. No one theory can cover all these cases; no one special *materies morbi* can explain cases so widely separated as a delirium happening after smallpox on the one hand, and a puerperal delirium on the other. Many of the causes put down in the text-books are entirely inadequate, in my opinion, to account for the delirium in the vast majority of cases. These causes are anæmia, exhaustion, mental and moral shock or strain, such as grief, fright, worry, etc. These may be contributory causes, and in the case of blood-impoverishment we have, probably, an important predisposing cause: but it seems to me that we want something more definite and tangible than worry to explain the death of a strong man in less than three days from the onset of the disease; something more

reasonable than an uncertain "malaria" to explain an acute delirious mania, with symptoms of meningitis, in a vigorous young woman.

In the cases following the exanthemata, and in the puerperal cases, an infectious poison is probably the immediate exciting cause. Clark gives details of forty patients with puerperal insanity, of whom nearly 50 per cent. had septicæmia or simple inflammatory trouble about the uterus. Clouston's puerperal cases showed a much higher range of temperature than any other class of cases—an "alarming result," as he thinks, of septic and inflammatory disorders. Since the time of Hippocrates this septic delirium following childbirth has been noted. The father of medicine himself reports a fatal case following a delivery of twins, in which case there were suppressed lochia, chills, insomnia, incoherence, convulsions, suppression of urine, coma, and death. Guislain distinguishes what he calls puerperal meningitis, which is characterized by sweats, fever, abdominal pain, and coma, and is evidently a septic delirium. With an increasing knowledge of septic disorders in childbed we shall probably hear more in time to come of sepsis as a cause of insanity in the puerperium.

But the cases in which we have a sudden explosion of delirium, without any recognizable source of infection, are not so easily explained—in fact, are not yet explainable at all. We are left here to speculation.

In Dr. Tull's case we found a perivascular engorgement. Possibly, ere long the case would have presented distinct pus-formation, and pus in the brain means infection. We stand to-day probably upon the border-land of a new domain in pathology, physiology, and, above all, animal chemistry.

It is premature to dogmatize, but it has appeared to me from a clinical study and comparison of this group of cases, that the symptoms point in the direction of an irritant poison. In his recent work Bevan Lewis has given the most complete and profound study of the morbid anatomy of the brain which has appeared in our language. It is noteworthy that he gives special prominence to the lymph connective tissue, and its "scavenger cells," which are found gorged with products of "intercellular digestion" especially in cases of rapid waste and deterioration of the cortical and neural tissues.

The microscope, however, will, probably, not continue to be the court of last resort in the study of mental disease. It is, after all, only an aid to the eye, and does not show things essentially invisible to the eye. It, probably, cannot show the vito-chemical reactions of the nerve-cell better than it shows the reaction between an acid and a base. It has already demonstrated so often, and in the hands of so many, the slight morbid changes in capillaries and neuroglia, as seen in these early fatal cases, that to repeat them again and again does not add to knowledge.

In the language of Montaigne: "*Je raconte, je ne juge pas*"—I relate these cases, I do not give final judgment upon them.

REMARKS ON ACUTE DELIRIUM.[1]

BY JOHN B. CHAPIN, M.D.,
SUPERINTENDENT OF THE PENNSYLVANIA HOSPITAL FOR THE INSANE, PHILADELPHIA.

HAVING been kindly asked by Dr. Lloyd to make some remarks upon the cases reported by him, it has seemed the better course to offer some general observations which they suggest. Few physicians from their own experience can have much to say of *acute delirium* (a term which Dr. Lloyd and Dr. Tull seem to prefer). As the disease is of rare occurrence, few physicians see a single case in the whole course of their practice, and typical cases are of infrequent occurrence in hospitals. Dr. Lloyd, like others, may have been surprised at the sudden onset of grave symptoms of an anomalous and unaccountable character, and at the steady progress of the disease to a speedy and fatal termination. I confess to having experienced such a feeling, as well as chagrin that all available measures applied for the relief of the patient seemed of no avail to prevent a fatal result.

As early as 1849, the French (Brierre) applied to cases of this class of diseases the term *acute delirium*. Dr. Luther Bell, during the same year, reported a number of cases with symptoms which he declared made out "a new form of disease," or a disease not previously recognized. From the rapid "emaciation," the appearance of sordes on the teeth and mouth, and the low condition of the patient, the term *typho-mania* was also used, suggested probably by the prevalence of typhus in the larger seaport towns at that time, and a similarity to the asthenic character of that disease. The Germans (Dr. Schüle, 1868) have recognized the group of symptoms presented by Dr. Lloyd's cases as a distinct form of disease to which they have applied the name *acute delirium* while in England, Dr. Blandford and others have used the term *acute delirious mania*, which seems to me appropriate and consistent with our usual nomenclature. The disease is a mania accompanied with active delirium.

If Dr. Lloyd has used the term *acute delirium* from what was apparently in his mind as to the possible etiology of these cases, a new field of broader speculation and investigation certainly is opened. That cerebral disease, with psycho-motor disturbance, has appeared even in an epidemic form from the

[1] Read before the Philadelphia Neurological Society, November 24, 1890.

inhalation of sewer-gas and the effluvia of old privy vaults is well known. The so-called meningitis at the Pittsfield (Massachusetts) Seminary, and at Aurora, New York, was due to the ventilation of privy vaults into the school apartments by closed passages. I myself have observed 40 out of 300 persons in one building prostrated in the course of twenty-four hours with cerebral and spinal pains, vomiting, sense of weakness, and several of the cases with delirium. So sudden was the onset that the illness was suspected at first to be due to poisoned food, yet was traced to the introduction of sewer-gas through an unused trap.

The frequent occurrence of cerebro-spinal and spinal meningitis in Philadelphia is of comparatively recent date, and is, I believe, to be largely attributed to the existence of drainage wells in houses and defective ventilation of sewer-pipes and water-closets.

While there is a strong presumption that meningeal disturbance, attended with delirium and motor excitement, results from infectious causes, *acute delirium* or *acute delirious mania* cannot be said to be caused by meningeal inflammation. The post-mortem appearances are of such a negative character that the centres of life, intellect, and sensation would seem to be mainly involved, no traces of physical disease and change being observed, as a rule. Yet, in the present state of our knowledge, with clues leading to new lines of scientific investigation, can any one wholly ignore the suggestion that Dr. Lloyd has presented?

While the sudden appearance of the prominent manifestations may suggest the existence of an active infectious process, it must be borne in mind that when we obtain a history it will be ascertained there has been a strain from overwork, worry of some kind, prolonged insomnia, or some moral shock. In other cases there are excesses and possibly other causes of which we can ascertain nothing. I can say of one case that a winter of social dissipation in Washington was a part of the history, and of another, frequent childbearing and constant domestic cross-purposes resulting in exhaustion and insomnia. The death of Horace Greeley from *acute delirious mania*, after the mental strain attending his political canvas is well remembered. The cases that I recall occurred in persons apparently well-nourished physically. It could not be said of them they were constitutionally neurotic, yet nervous heredity has often been noticed. After a few days of noticeable hurry and worry about small, non-essential things, which may not be recalled until the disease has developed, and may not even attract attention at the moment, and without pronounced prodromic symptoms, the patient may awaken in a confused or delirious state. There has been no chill, vomiting, headache, or spinal pains. The attention of the patient may be roused and held for a brief period in exceptional cases, but as a rule even this is impossible. The mental state is one of profound confusion, or absorption in centric ideas. Hallucinatory disturbance of several, or all, of the senses is the prominent manifestation. There is also excessive motor disturbance—the patient is in constant motion—and there is frequently a tendency to gyratory motions. The delusions are those of fear, apprehension, or suspicion, of persons and food, and there is much difficulty in the administration of nourishment. The patient does not usually talk in a loud and demonstrative manner, but in a quiet tone, with little reference to surrounding objects or persons—much like the conversation at one end of a telephone. The total absorption of the mind of the patient in centric ideas, indifference to all surrounding objects, and inability to attract the attention in these and all similar cases, are unfavorable prognostic signs; but when the delusions have reference to and are connected with surrounding objects and persons, the case is more hopeful. The pulse shows a wide range, as from 100 to 120 and 140 in a brief interval of time. The temperature reaches 104°, or even 106°, usually 100° to 102°.

There are also distinct remissions, like lucid intervals of a few hours' duration, in which the patient seems for the time rational, and the pulse and other conditions resume a normal state. Possibly, but certainly rarely, the disease may suddenly end in this manner. If, however, there are exacerbations and remissions of all of the symptoms, if there are profound delirium and insomnia, if the attention cannot be roused, if the several senses are more or less involved, if there is great motor disturbance, if, at short intervals, there is a great variation of the pulse, if the fingers tend to the palms, the prognosis is decidedly unfavorable. Death may take place in two or three days; but if life can be preserved for from ten days to two weeks, the stage of acute delirium subsides, but the maniacal stage continues, with chances that in one or two months recovery will take place. It is the general experience that when death does not occur in the early stage recovery follows rapidly and completely, and without a stage of succeeding dementia.

The probabilities in a case of acute delirium, or acute delirious mania, are against recovery, and this fact should be borne in mind if the question comes up whether the patient should at once be sent to a hospital, or whether there should be a delay of a few days. Undoubtedly the mortality from this disease was formerly greater than now. The rapid waste of tissues, the dry tongue, the sordes on the teeth, and the general asthenic condition, are more promptly met now by a liberal administration of food and stimulants. Then, again, the new hypnotics can

be used safely and effectively, without the necessity of administering drugs, that sometimes do more harm than good by intensifying the delirious condition, and developing a new pathological state. I have seen hyoscine produce sleep, and quiet the excessive restlessness and struggling characteristic of this disease.

In the progress of the disease there will be observed a tendency to sluggish circulation—a stasis of the capillary circulation. This is a symptom of serious import, indicating the extent to which the vasomotor system is involved. It is important to be able to combat a tendency which is a precursor of a fatal termination. I have in three cases seen this condition removed by packing the patient in hot wet sheets. In each case the supposed hyperæmia of the brain seemed to be relieved, the general circulation was improved, there was diaphoresis and a free discharge of urine.

In our present state of knowledge, anything that may be said of the pathology of a disease that leaves no appreciable traces is partly speculation. The cases of this disease furnish a history of strain from overwork, worry and anxiety, shock, or of some profound emotional disturbance at some period, such as may produce an arrest, alteration, or disorder of nervous nutrition. As the deficient nutrition of the nervous mass and the asthenia and collapse which characterize these cases are due to a deterioration of the quality of the blood, and to the state of the cerebral circulation, the state of the patient, as we observe him, is that of mental and physical incoördination. There are successive explosions of psychic and physical force, such as may be supposed to arise from the suspension and disorder of the inhibitory functions. As the tendency is to death from asthenia, the indication for treatment from this point of view is to support the patient during the existing paroxysm, and the prolonged use of tonics and rest during and after convalescence.

A CASE OF ACUTE DELIRIUM.

BY M. G. TULL, M.D.,
OF PHILADELPHIA.

THE patient, Charles P., aged thirty-nine years, was a farmer until eight years ago; since then has managed a switch-board in the tower of the Philadelphia, Wilmington and Baltimore Railroad, at Gray's Ferry Station, and at the same time carried on a grain and grocery business. When nine years old, he fell from an ox-cart, which caused bleeding from the left ear for one day, and the ear remained permanently deaf. His subsequent history was that of unvarying health. In appearance he was a man of typically fine physique.

On August 16th he spent the day at Atlantic City, where he stayed in the water for four hours.

On August 24th, at 6 A. M., I was called to see him. I found him tossing to and fro on the bed, flinging his arms about, and with a vacant expression of the eyes. His only symptom of distress was a constant tendency to move his hands toward the bladder. He was apparently semi-conscious. Thinking that the condition might result from retention of urine I catheterized him, and found the urine normal in color, odor, and quantity. I carefully examined for albumin, with negative results. In fact, I could find no evidences of organic disease, and was at a loss for a diagnosis. This condition continuing during the morning, I suggested a consultation with Dr. J. Hendrie Lloyd in the afternoon. Dr. Lloyd pronounced the symptoms hysteroidal mania, and he also could find no evidence of organic disease. The pulse during this time varied from 75 to 88, the temperature from 100° to 101°. His skin was very dry. I had given $\frac{1}{4}$ grain of morphine with $\frac{1}{60}$ grain of atropine hypodermically to control restlessness. I then employed steam-baths, and pilocarpine both hypodermically and by the mouth. After the steam-bath was continued for two and a half hours his skin became moist. The condition of the patient continuing unrelieved, in deference to the apparent wishes of the family, who were convinced that there was some ear-trouble, because previously to the attack he had complained of pain about the right side of the head, I requested Dr. J. B. Deaver to see the case. He joined Dr. Lloyd and myself in consultation, Sunday night, August 24th. We agreed that the symptoms were simply maniacal, and that there were no evidences of organic disease.

On Monday, August 25th, the same conditions persisted, except that the patient seemed more conscious. Between the paroxysms he was able to sit on the bed and urinate, but he passed very little urine and with great difficulty. His temperature varied from 100° to 103°, and pulse from 75 to 88, his respiration averaging 24. During this whole period the conjunctival reflexes were present, and his attention could be partly fixed by a quiet, determined effort. On Monday, at 11 A.M., Dr. Lloyd again saw him with me, and considered that the diagnosis of non-organic disease was confirmed. We again put him on opium and small doses of belladonna by the rectum. During Monday night, August 25th, the patient rapidly became worse. I was sent for at 6 o'clock A.M., when I found him dying, his pulse having increased to 105, and his temperature to $103\frac{2}{5}$°. At 8 A.M., August 26th, he died.

That afternoon the autopsy, kindly conducted by Dr. J. A. Davis, assisted by Dr. Brinkman, in the presence of Dr. Lloyd and myself, revealed a condition apparently of incipient meningitis. The temporal bone was not diseased.

After the man's death I was informed by his neighbors that his temper had seemed decidedly more irritable and aggressive than usual for some time past, and that he had been working eighteen hours daily.

ON THE RELATION OF ECZEMA TO DISTURBANCES OF THE NERVOUS SYSTEM.[1]

BY L. DUNCAN BULKLEY, A.M., M.D.,
ATTENDING PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL.

No careful medical observer or thoughtful student of medicine can rightly doubt or ignore the part which the nervous system plays in relation to many diseases of the skin, although the exact connection and causal relations between nerve-disease and skin lesions may not always be apparent or satisfactorily explained. The intimate association of certain skin affections with, and their dependence upon nervous elements have passed beyond the basis of personal judgment and experience, and rest upon sound anatomical, pathological, and clinical grounds, which are being confirmed and strengthened daily.

Time and space fail us to detail here the proofs of this statement, most of which are more or less familiar to all; the careful and thorough writings of the many observers to be mentioned later on are full of demonstrations of the neuro-pathology of various diseases of the skin, and the present writer has on several occasions elaborated the subject, giving clinical illustrations of the same.[2]

It suffices, therefore, for our present purpose to accept the fact that the nutrition of the skin and of the cells composing its structure is under direct nervous control, so that under proper nerve-influence the processes of health are carried on, while under perverted nerve-action many pathological changes may take place in the skin, as well as in other tissues.

Fully accepting this basis of a possible neuro-pathology of lesions in the skin, it remains for us to study how far clinical and pathological facts point toward this element of causation for the eruption, phases of eruption, or disease to which the name of eczema is given.

In approaching the subject of the relation of eczema to disturbances of the nervous system, the questions naturally arise: What is eczema? What is it that constitutes the disease under consideration? What is it that determines that the skin lesions seen in any particular individual are eczema, and not some other affection? What are the real essence and nature of the disease? Is it purely a skin affection, consisting of certain changes in the cutaneous tissue, from many causes, or is there some underlying condition, habit, or state of the system, which determines the pretty uniform set of cutaneous symptoms which we call eczema? It would seem that these questions should be definitely answered before we could make any great progress in a study of the disease or its treatment, and it is hoped that the present discussion may aid somewhat in their solution. But everyone familiar with dermatological literature knows that they have been the theme of countless discussions, and that widely-divergent opinions have been expressed by those of large experience in the disease in all countries, so that even to-day there is no universally accepted view as to the ultimate nature of eczema.

It would be out of place to enter here at all fully into the discussion of these topics, or to consider at length the morbid conditions of the skin to be included as eczema, but a few words must be allowed in order to understand rightly the basis of our study.

We know and recognize eczema by its cutaneous phenomena, for it cannot be said that it has any other absolute symptoms than those found upon the skin. But still, polymorphous and *bizarre* as those appearances upon the skin often are, simulating at times many other quite different cutaneous affections, there is a group of symptoms which are universally recognized as belonging to eczema, and of a thousand cases so named by a competent dermatologist, the diagnosis of very few would be questioned by others similarly qualified. A brief definition which would cover every case of eczema, or a short description of its forms and phases as seen in persons of various ages and on different parts of the body, would be very difficult to give; and, after all, it is only the composite picture, including many features belonging equally to other affections, that we designate as eczema.

But, in connection with various cases of eczema, we often meet with other phenomena also than those upon the skin—that is, we find disturbances or disease of other organs of the body, which we learn by clinical observation to associate more or less closely with the disease under consideration, and which are found by experience to be of importance etiologically. These, furthermore, are seen to improve or disappear with the hygienic and general treatment or measures directed to the eruption, and yet none of them can be called absolute symptoms of the disease, or essential features of the eczema. The elements referred to are such as anæmia, lithæmia, the strumous or gouty habits or conditions, high arterial tension, and also various derangements of

[1] Prepared by special request, to open a discussion on eczema at the Tenth International Medical Congress, Berlin, 1890.

other organs, mainly the digestive tract, liver, and kidneys, together with certain *nervous phenomena;* all these may be well- or ill-defined, and may either obtrude themselves or be discovered only after close investigation.

As remarked before, none of these elements have been proven to belong properly and absolutely to eczema, but still from accumulated clinical experience they must, singly or combined, be considered factors in the production of the disease. If, however, we are pressed to a single answer as to the real nature of the disease, we are obliged to state that we as yet know very little in regard to the true and fundamental cause of eczema: why one person should have it when another individual escapes, who is apparently in the same or worse condition in respect to the derangements of health mentioned, cannot be explained.

The real reason, however, possibly lies in the local condition or constitution of the skin itself, which renders it liable to take on this peculiar form of inflammatory action, either upon the application of external irritants, or from neurotic or other derangement of its nutrition from within. To this condition or state of the individual in whom these changes are likely to take place, under the same or other causes, we apply the term *eczematous*, without indicating thereby any exact or particular disease or known alteration of the system, simply for the reason that we do not know what that is.

I think, therefore, that in studying the relation of eczema to disturbances of the nervous system, or its relation to any other derangements, functional or organic, of any portion of the economy, or in considering the effects of local agents in producing the eruption, we should be very careful to discriminate between predisposing and exciting causes, and give due weight to each: *post hoc ergo propter hoc* is a very seductive and dangerous form of reasoning in medicine, but one which is often unconsciously, or sometimes ignorantly, applied.

Thus, when we see an eruption, which we call eczema, apparently follow or depend upon some nervous disturbance, we should carefully consider (1) if, possibly, it may be only a coincidence; or (2) that the two may depend upon one common cause; or (3) that the nerve-disturbance may have excited the eruption in one previously predisposed thereto; or (4) that the effect of the former may be very remote, putting in action a train of systemic changes which may end in inducing the eruption. In none of these instances could we properly speak of the nerve disorder as the cause of the disease. Even when the eruption seems to follow pretty directly upon some severe nerve strain, shock, injury, or disease, much caution should be exercised in ascribing an immediate causative connection, for how rarely do we find these conditions followed by the development of eczema; and, on the other hand, how very few of the multitudes who suffer from eczema ever exhibit any causative elements pointing toward the nervous system. To my mind the proof is infinitely stronger in regard to many other of the internal and general causative elements mentioned, and in a far larger proportion of cases, than is that regarding the connection of eczema with disorders of the nervous system.

But still, while it is thus urged that caution is necessary before accepting any etiological relationship between eczema and nervous disturbances, it must yet be granted that the weight of evidence is very strong in favor of such relationship to a greater or less extent in certain cases, and that possibly, as our thought is turned in this direction, it may become even more evident than it is at present; and certainly it is wise to regard the neurotic aspect of many cases of eczema in connection with the therapeutics of individual patients.

There is one clinical feature or symptom in eczema which would seem to point to a neurotic element in the disease, even to the most superficial observer, namely, the itching, without which the disease may hardly be said to exist. Not only is the sensation of pruritus a common and severe symptom when the eruption is pronounced, but even before any amouut of lesions are appreciable on the skin, and often long after they have ceased to be prominent, the itching may prove most distressing; and all recognize that scratching to relieve itching is a most prolific cause of the development and increase of the eruption. How far the itching is a primary feature, and how far it results from pressure upon nerve filaments by effused fluid or swollen cells, it is impossible to state; it is certain, however, clinically, that in an acutely-developing vesicular eczema there is much relief from the itching when the fluid reaches the surface, either spontaneously, or by artificial aid; on the other hand, some of the most distressing and inveterate pruritus is found in certain cases of erythematous eczema about the face, where there is but little infiltration of tissue. This latter form is very apt to occur in elderly persons, and in those nervously broken down.

For many years writers have recognized, to a greater or less extent, the dependence of certain cases of eczema upon nerve-disturbance or disease, and in addition to the generalized statements found in text-books to this effect, there are a considerable number of recorded observations in different countries which tend to show the clinical and pathological soundness of this view. It will be our endeavor to classify these observations, and to present, as briefly as possible, such evidence as seems of special interest.

There are so many points to be considered in

studying the influence of the nervous system in the production of eczema, that it is by no means easy to weigh the relative effect of the various nerve lesions or disorders which have been reported in this connection, nor to distinguish clearly the real mode in which the deranged neurotic element operates; at present much relating to the subject is mere conjecture, waiting for verification or refutation with the light of advancing science. But as all work can be best carried on when there is a skeleton basis on which to arrange proof, we may attempt to construct a scheme about which clinical and pathological observation and research may build as opportunity offers.

With this view, and with the material at hand, we will consider the relations of eczema to disturbances of the nervous system under the following heads:

1. Anatomical, physiological, and pathological grounds for such a relationship; and

2. Clinical grounds, based on recorded observations.

1. *The anatomical and physiological grounds* for a nerve-relationship in eczema need not detain us long. All are familiar with the very abundant nerve-supply of the skin, and with its distribution even among and into the cells of the rete Malpighii, and into the cells composing the glands of the skin, and that nerve-fibres are very freely supplied even to the hair-follicles and lymph-spaces, as shown especially by Arnstein.[1]

The influence of the vasomotor nerves, both in the normal regulation of the blood-supply and nutrition, and also in the production of morbid states, is now so well recognized both in regard to the skin and other organs that it needs but to be mentioned.

We are also well aware of the control which the sympathetic system exercises over various processes of the body, healthy and morbid, including the skin and its glands, as has been so carefully elaborated by Eulenberg and Guttman,[2] E. Long Fox,[3] and others. The neurotic aspects of many skin affections have also been admirably worked up of late years by Rendu,[4] Testut,[5] Leloir,[6] Schwimmer,[7] and others,[8] so that now there is no reason to doubt that from anatomical and physiological grounds changes may take place in the skin through the medium of the nervous system.

The direct anatomico-pathological grounds for recognizing a nerve origin of eczema have unfortunately been studied but little, and the subject offers a promising field for future research. The condition of the nerves in the affected skin in acute and chronic eczema, also the state of the conducting nerves and of the cord, likewise that of the sympathetic nerves and ganglia, have thus far been hardly at all studied. The much-quoted observations of Colomiatti[1] are almost our sole basis of knowledge regarding the condition of the cutaneous nerve filaments in eczema. It will be remembered that in a number of cases of eczema, mainly of the papulo-squamous type, he reports finding material changes in the cutaneous nerves, while in cases which had been partially or wholly cured, he claimed that the nerve-tubes had been to a large part restored to health; but he was unable to observe the various changes of regeneration. Leloir[2] states that in two cases of eczema in which he examined the nerves, he found both the nerve-filaments and their sheaths normal; but in a later communication[3] he says that he has verified the observations of Colomiatti.

2. *The clinical grounds* for the assumption of a relationship between eczema and disturbances of the nervous system are much more full and interesting, and have been dwelt upon by many observers.

We may divide our study of this portion of our subject into five general heads, considering eczema as it is related to

1. Neurasthenia or nerve-exhaustion.
2. Nervous and mental shock.
3. Reflex phenomena: (*a*) of internal origin; (*b*) peripheral.
4. Neuroses: (*a*) structural; (*b*) functional.
5. Encephalopathy and myelopathy.

1. NEURASTHENIA OR NERVE-EXHAUSTION.

Neurasthenia, or general nervous exhaustion or depression, must be placed first in the list of neurotic conditions associated with or causative of eczema, since in this is found a predisposing element in very many cases of the disease; moreover, it undoubtedly

lies at the bottom of many instances in which other nervous conditions act as the exciting cause of the eruption, as will be mentioned later on.

While this term neurasthenia is somewhat indefinite, and as a disorder it may be said to have no pathology, yet practically the condition does exist, especially in America; furthermore, a general nerve-exhaustion, from many causes and taking many shapes, is not infrequently found in a certain class of eczema patients, and does, to all appearances at least, have much to do with the genesis and continuance, or recurrence, of the eruption in many cases.

Clinical proof of this could be furnished in abundance, and numberless cases could be detailed in which eczema, more or less severe and general in character, followed directly upon prolonged nervous strain, such as long attendance upon the sick, distressing or exhausting work of any kind, sleepless nights from worry or anxiety, etc. A few illustrative cases, some of which have already been mentioned in print, by the present writer, may be briefly alluded to:

An unmarried lady, aged fifty-three years, was the executive officer of a charitable institution, and her duties were arduous and exacting. On Tuesday of each week she was particularly tried on account of the weekly meeting and inspection of a board of lady visitors, and that night was often sleepless. Her eczema of the face and hands was always aggravated on the succeeding morning; indeed, the eruption which would often yield very satisfactorily to treatment during the week, would burst out afresh on the Wednesday morning succeeding the visit. This had been the case for some months before I saw her, and was verified by myself again and again.

A prominent clergyman, aged fifty-two years, had for many years an eczema of the head and face, which was always greatly aggravated on Monday after the Sabbath's mental work and strain. This I myself observed on a number of occasions. The same occurred sometimes during the week, whenever extra work, such as a public address, was called for.

In another case, that of a lady, aged twenty-two years, any nervous excitement or household disturbance and hysterical crying would be followed by a fresh outburst of eczema of the hands.

In numbers of instances I have seen business or legal worry followed shortly by eczema. Mentioning the matter to an exceedingly intelligent gentleman, now aged forty-two years, whom I have seen off and on with eczema for ten years, he remarked on the truth of the observation, and said: "You may quote me as a striking illustration of the effect of nervous strain in producing eczema again and again."

Some knowledge in regard to the effect of nervous strain in the production of eczema may be learned, I think, from a study of the statistics of cases, especially in private practice. In the accompanying tables—I. and II.—are given the sex and age of 5000 cases of eczema under my personal observation, arranged in semi-decades, but time permits only one or two points to be noticed. It will be seen that about one-half of the cases were in males—nearly 54 per cent.; but if the tables be examined more closely, it will be found that among the private patients the males formed a much larger proportion, namely, almost 59 per cent. If now we analyze this more closely, we find that during the period of manhood, from thirty to fifty years of age, when the greatest strain of life comes on men, the number of males in private practice is about double that of females.

TABLE I.

TABLE OF PUBLIC AND PRIVATE ECZEMA CASES.

AGE.	PRIVATE.			PUBLIC.			
	Male.	Female.	Total.	Male	Female	Total.	Grand total.

40 " 45 "	124	63	187	76	107	183	370
45 " 50 "	113	67	180	76	121	197	377
50 " 55 "	97	54	151	94	108	202	353
55 " 60 "	90	41	131	64	69	133	264
60 " 65 "	67	31	98	52	49	101	199
65 " 70 "	48	14	62	39	31	70	132
70 " 75 "	34	11	45	31	13	44	89
75 " 80 "	16	6	22	8	5	13	35
80 " 85 "	4	4	8	1	2	3	11
85 " 90 "	2	2	4	...	1	1	5
90 and more	2	...	2	1	...	1	3
	1271	895	2166	1527	1523	3050	5216

Looking now at the column relating to male patients in private practice, we find that between ten and twenty years of age there were but 63 cases, whereas, in the next decade there were 154 cases, or about two and one-half times as many; while during the next decade, that between thirty and forty years of age, there were no less than 264 cases, or more than four times as many cases as during the developmental period—from ten to twenty years—before the cares of life begin to weigh heavily on man. The next decade, that between forty and fifty years, shows also a large number, namely, 237 cases. Thus, between the ages of thirty and fifty, when the nervous strain of life comes most on men, the disease is enormously increased, there being no less than 501

cases, or nearly 40 per cent. of all the instances of eczema in males, in private practice, during this period.

The increased proportion of cases of eczema in males during this period is also forcibly shown in Table II., where the proportion of eczema cases to living people is shown in periods of five years each. Here we see that while the percentage of persons living between the ages of twenty-five and thirty years is only 7.5, the proportion of the eczema cases occurring during this five years is 8.3, and the increased ratio is shown in each semi-decade up to sixty years of age.

TABLE II.

COMPARISON OF PERCENTAGE OF ECZEMA PATIENTS AT DIFFERENT AGES WITH THE PERCENTAGE OF INDIVIDUALS ALIVE AT THOSE AGES, AS SHOWN BY THE CENSUS.

Ages.	Per cent. of ages of all persons.	Per cent. of eczema patients.	Relation between the two.
Under 1 year	2.2	6.7	+
1 to 2 years	2.0	3.8	+
2 " 3 "	1.9	3.2	+

90 and over	0.07	0.056	—

Exactly how this nerve-strain and nerve-exhaustion operate to induce eczema cannot now be stated with certainty, but, clinically, the fact appears very certain when cases are studied with sufficient exactness. This view is also supported by many writers, and finds corroboration in such expressions as the "nervous debility" of Wilson, and "faulty innervation" of Hebra, Tilbury Fox, and others. It is interesting to note that the elder Hebra[1] expressed himself convinced that "faulty innervation played the principal *rôle* in the production of eczema"; although now so often quoted as a localist, he recognized the internal and general causation of many skin-affections to a much greater extent than is commonly believed. Nikolski[2] has recently reported some cases illustrating the neurotic origin of eczema.

Finally, the therapeutic measures which are of service in many cases of eczema point strongly to a general neurotic causation. Arsenic, strychnine, quinine, preparations of phosphorus and iron, cod-liver oil, and other remedies which are of use in neurotic states, form the basis of much of the internal treatment of eczema; ergot also, as especially shown by Witzel,[1] often proves very valuable, acting, as it is claimed, through the vasomotor nervous system. Electricity likewise, in the form of general galvanization, has been reported on favorably by Beard,[2] Fitch,[3] Morton,[4] Eloy,[5] and others. It is quite possible, also, as suggested by Tilbury Fox,[6] that the beneficial effect of sedative local measures, used early in acute eczema, may be ascribed in part, at least, to a reflex neurotic action.

(To be concluded.)

A NEW MODE OF EXHIBITING SULPHONAL.

BY DAVID D. STEWART, M.D.,

LECTURER ON, AND DEMONSTRATOR OF, DISEASES OF THE NERVOUS SYSTEM, IN THE JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO ST. MARY'S AND ST. CHRISTOPHER'S HOSPITALS, ETC., PHILADELPHIA.

UNQUESTIONABLY the great disadvantage of sulphonal over other recently-introduced hypnotics is its insolubility and consequent slowness of action. As ordinarily administered, dry upon the tongue, or suspended in mucilage, etc., the result, in most cases, is unsatisfactory. Even after a decided dose hours often elapse before sleep is obtained, and, usually, a condition of very annoying semi-somnolence is maintained throughout the greater part of the subsequent day. Unpleasant effects of this sort are so frequent that many physicians are deterred from prescribing what has proved in my hands the most satisfactory of the newer hypnotics. These effects obtain because of the very slow diffusion of the drug when taken in a state of simple suspension, the whole amount not entering the circulation for many hours after its ingestion.

I desire to call attention to a more satisfactory mode of administering sulphonal; a method that occurred to me when having occasion to take the drug a year or more ago, and one which has subsequently afforded me results in practice not in the least obtainable by its use in the common way. My method is as follows: I direct that just before retiring the sulphonal powder be well stirred in a

glass two-thirds full of boiling water (about six fluid-ounces) until entirely dissolved. The water must be boiling, and to insure that it is at the boiling-point when brought in contact with the sulphonal, it had better be heated on the spot. It can be boiled in a tin-cup over the gas, or over a spirit-lamp. After the sulphonal has entered into solution, which will occur in a moment or two if it be well-stirred, cold water may be very cautiously added to reduce the liquid to a drinkable temperature, which, if the patient is accustomed to taking hot fluids, *will be one not sufficient to cause the slightest precipitation of the drug;* or the hot solution of sulphonal may be permitted to cool to this temperature, the cooling process being facilitated by continued stirring. To insure success the sulphonal must be taken *wholly dissolved*, and the hotter the solution is drunk the better. It is surprising to one accustomed to prescribing this hypnotic in suspension several hours before bed-time, to allow for what has been called the period of therapeutic incubation, to note the prompt and satisfactory result of this simple manœuvre. The hot solution dilates the gastric vessels and stimulates them to rapid absorption, so that diffusion takes place from the stomach probably before slight or any precipitation of the drug occurs; entirely unlike the result that follows when the sulphonal is ingested in a state of simple suspension. In the latter case gastric absorption can scarcely occur, and hours are perhaps consumed before the whole amount taken enters the blood. The period of therapeutic incubation is practically done away with. Sleep results in most cases in a very few moments, and seems to be more profound and dreamless than that from a larger dose taken in the ordinary way, and the annoying condition of drowiness usually present on the subsequent day is scarcely felt if the dose be properly graduated. The hot solution, which has a slightly unpleasant taste from the dissolved sulphonal, may be rendered decidedly palatable by the addition of a tablespoonful of some such *liqueur* as *crême de menthe* ("green mint"), which, apart from its efficiency in this direction, will probably tend to promote still more rapid absorption of the drug. To obtain an immediate and altogether satisfactory result from this method it is desirable that the stomach be empty or at least comparatively free from food, so that precipitation be not favored and absorption delayed by the entanglement of particles of sulphonal and undigested food, but as it is unnecessary to take the dose until the retiring hour there will usually be no difficulty from this.

1231 WALNUT STREET, PHILA.

Obituary.—John Marshall, F.R.C.S., F.R.S., LL.D., the well known English author, anatomist, and physiologist, died January 3, 1891, in London, aged seventy-three years. His death was due to acute bronchitis.

AN EXPERIMENTAL AND CLINICAL STUDY OF ERGOT.[1]

BY JOHN C. HEMMETER, PH. D., M.D.,
OF BALTIMORE, MD.

PART I. *Experimental.*—Our knowledge of the physiological action and therapeutic application of such a complex drug as ergot, must be based upon a perception of relations. In no department of experimental therapeutics do we meet with such manifold and contradictory results, or with more widely-digressing theories than those concerning the action of ergot. This is especially true in the investigations that have hitherto been made relating to the nature and cause of the contraction of the pregnant and non-pregnant uterus, which is produced by this drug. Up to the present time it has not been established whether the action of ergot in this case is a peripheral or central one; that is, whether ergot acts by innervating the uterus through the spinal cord, or directly on the muscular fibre of the organ.

H. C. Wood, in the last edition of his *Treatise on Therapeutics*, admits the uncertainty, but thinks that the drift of present evidence is toward peripheral action. The only evidence which he quotes to base this view upon is that of Boreischal,[2] who in several experiments succeeded in producing violent contractions of the uterus after dividing all of the nervous connections of the organ. Opposed to these results we find those of A. Wernich,[3] who found that no contractions of the unimpregnated womb were produced by ergot after section of the spinal cord. Wernich made only two experiments to decide the point, and any possible force his result might have is destroyed by the fact that he himself does not attribute much importance to it, because the death of his animal took place immediately after the experiment as a result of the operation.

T. Lauder Brunton, in his *Pharmacology and Therapeutics* (1885), intimates that ergot possibly acts like ammonia—producing contraction of the uterus after all nervous connections have been divided—but on the whole gives no experimental evidence for deciding the point in question.

Rosenbach[4] is inclined to accept a direct and local action of ergot upon the muscular tissue of the uterus, indirectly causing contraction by bringing on acute anæmia of the organ.[5] C. Binz holds that as long as we have no better proofs than the present, to believe the opposite we must accept (mainly from clinical observations) that ergot

[1] Experiments were made in the Biological Laboratory of Johns Hopkins University, Baltimore.

[2] Loc. cit., p. 548.

[4] Arzneimittellehre.

[5] Pharmakolog. Untersuchungen, Wurzburg, 1879, Bd. iii. S. 78.

directly acts upon the uterus in producing contraction, and not by innervation through the spinal cord.[1] Röhrig,[2] again, is directly opposed to this opinion.

These contradictory statements may be partly explained by the fact that the uteri of different animals vary greatly with regard to their irritability and to the manner in which they respond to stimulations by general contractions.

The uterus of the dog and the cat is not very irritable, and responds only to very strong stimulations, and even then rarely by general contraction. The uterus of the rabbit, however, is very irritable, and at times exhibits spontaneous contractions when no direct stimulus has been employed. Secondary circumstances, such as manipulation incident to the vivisection, opening of the abdominal cavity, and the mere access of the air to the organ are sufficient to cause it to contract. These contractions soon come to a close and then the uterus lies perfectly at rest. It is in these periods of rest that the experiments with stimulation should be undertaken. Schlesinger[3] has called attention to the availability of virgin rabbits for these investigations. In these animals one generally finds the womb completely at rest though responding promptly to applied stimuli. It is not difficult to distinguish the uterus of a virgin animal from one which has borne young. In nine out of the twelve experiments which I made concerning this subject, I made use of so-called virgin rabbits.

The contraction-waves of the uterus generally pass over the muscular layers of the organ in a definite direction; as a rule, they begin as regular peristaltic movements at the abdominal end of the tubes and horns and radiate toward the os, or in rare instances beginning as antiperistaltic movements at the os, they progress over the body of the uterus, shortening it considerably, and run out toward the tubular end of the horns. In addition to these general peristaltic movements, one can notice after circumscribed irritation of the organ, certain local, more or less sharply-defined, circular contractive narrowings or constrictions, which Röhrig, I think, has designated as strictures; these may progress outward over the horns in alternating directions. Finally, by constant increase of the stimulation, the peristaltic contractions as well as the strictures may pass into spasmodic or tetanic contractions under which the uterus may assume an almost erect position. Some of the animals upon which I experimented were pregnant; the uterine contractions in these cases were very intense and lasted from one hour to an hour and a half (whilst in non-pregnant animals they cease in from three to six minutes) when the uterus fell into a state of repose. These periods of repose must always be waited for, before any experiments with stimulation can be undertaken.

A part of the discrepancies in the opinion of the investigators mentioned might be explained by the fact that the quality and efficacy of ergot and of its preparations obtainable in pharmacies vary greatly. This is a misleading circumstance, both in practice and in the laboratory, because no definite chemical tests are known which can be used to establish the therapeutic value of a given sample. In a large number of therapeutic substances we are enabled to test their value by simply determining in them the percentage of definite, crystallizable alkaloids or other principles upon which the therapeutic action of the drugs chiefly depends. In ergot the case is different. Its constituents are numerous, and judging by the widely-differing and often contradictory results obtained by different investigators, are at best, not well defined. This is most likely due to the fact that nearly all the constituents are uncrystallizable, and hence are very difficult to separate without contamination with other extractives soluble in the same menstruum. Nor does the literature on the subject up to the present day enable us to conclude definitely to which of these rather indefinite organic principles the peculiar therapeutic properties of ergot are due. It seems probable from a study of the results of Buchheim, Dragendorff, Zweifel, and recently of Kobert, that at least three of its constituents are of importance. These are sclerotic acid, which Kobert designates as ergotinic acid, scleromucin, and the cornutin of the latter investigator, who has recently called our attention to a new body in ergot, namely, sphacelinic acid. It is also established that the characteristic physiological effects of the drug are not due to either one of these bodies, but to a combination of them. Thus ergotinic acid produces contraction of the arterioles, but not of the muscular fibres of the uterus. According to Kobert, the constituents which produce contraction of this organ are cornutin and sphacelinic acid,[1] but the whole subject of the active ingredients still remains enveloped in much uncertainty.

As the watery infusion of fresh ergot (this having been used by former investigators) was found to undergo changes very rapidly, I concluded to resort to the fluid extract of ergot, but found this as obtained from various sources very variable, both in physical properties and therapeutic efficacy, some of the specimens having a very offensive odor. In

[1] Vorlesungen über Pharmacologie, Bd. xi. S. 298.

[2] Arch. f. Pathol. Anat., Bd. lxxvi. S. 23.

[3] Uber die Centra der Gefäss und Uterus nerven, Medic. Jahrbücher, 1874, Heft 1.

[1] See also Buchheim, Archiv. f. exper. Path. u. Pharmak, 1874, Bd. iii. S. 1. Zweifel, ibid. Bd. iv. S. 387, and Dragendorff u. Podwissotzky, ibid. Bd. vi. S. 153.

two German preparations of ergotin and one liquid ergotin prepared in Basle, Switzerland, and specially recommended by the manufacturer for hypodermic use, a very unpleasant fœtid odor reminding of decomposed organic matter was noticeable, and the last-named used hypodermically proved very irritating, causing an abscess in a patient suffering from goitre.

Some of the secondary results in the experiments upon animals, which I shall presently describe, were undoubtedly caused by the impurities of the ergot used. (Emboli in the pulmonary and cardiac circulation.) My attention was at last called to a form of liquid ergotin made in Baltimore by Sharp & Dohme, which gave evidences of being a standard preparation, both in clinical and experimental application. I have had some of this ergot in my possession for nearly ten months (since February 3, 1890). It has deposited no sediment, has a fresh, pure odor, and is very effective. This ergotin solution, which is probably the most concentrated liquid preparation of ergot that can be obtained, has since become known under the name of ergotole, to distinguish it from the numerous and widely-differing preparations sold under the name of ergotin. In the experiments to be described this form of ergot was used, together with two forms of fluid extract of ergot, the officinal containing hydrochloric acid, the other no acid, which, however, were more bulky.

After the injection of 1 c.c. of fluid extract of ergot (about 16 minims), the capillaries and arterioles in the omentum of a large rabbit could be seen to contract within from five to eight minutes, and the uterus showed peristaltic contractions. On the other hand, 0.25 c.c. (4 minims) of the liquid ergotin just described produced the same effect on the arterioles in from two to three minutes (rarely five minutes), and the contractions of the uterus were more active and followed each other with greater rapidity. The ergot in both cases was diluted with the same quantity of distilled water, and injected into the jugular vein in preference to the hypodermic method, as the absorption of solutions of ergot from beneath the skin in animals is very slow. This does not seem to be the case in the human being. The rabbit omentum or mesentery was gently spread over a warm stage, and constantly kept under warm normal salt solution; the microscopical examination was made with a Zeiss objective D, ocular A. The irritation was applied in the form of the constant and also the interrupted current, but chiefly the latter, by making use of an induction coil. The time elapsing between stimulation and contraction was measured by a second metronome and at times by a watch. The electric stimulations referred to were employed to test the state of excitability of the uterus. The objects of the experiments which will now be described were:

1. To determine whether the contractions of the uterus by ergot is of centric or peripheral origin.

2. Whether the peristalsis of the intestines is increased or diminished by ergot. If increased, whether this be due to a centric or peripheral action of ergot.

3. Whether the cause of the contraction of the bloodvessels in the omentum is central or peripheral.

4. Whether ergot produces a rise or a fall of blood-pressure. Whatever change occurs, is it due to an action on the heart and arteries or on the spinal cord.

5. The action of ergot on temperature.

First. We will first take up the question of the centric or peripheral origin of the contractions of the uterus. As both chloroform and ether reduce the peristaltic contractions of the uterus in animals, the rabbits used for this purpose were curarized and given, in some cases, a rectal injection of morphine. The curare must be injected in very small quantities, otherwise it will also affect the uterine contractions.

It was necessary in order to solve this problem to isolate the uterus from all nervous connection and then observe whether it would contract after injecting ergot into the jugular vein. It has been established beyond a doubt by Goltz[1] that the centre for innervation of the uterus is located in the lumbar region of the cord. For after cutting the cord at the first lumbar vertebra in a female dog, nine months old, and allowing the wound to heal, the animal in course of time became pregnant and brought forth normal healthy pups. This experiment proves, it is true, that the lumbar cord is sufficient to innervate all these processes, but not that there are no centres in the cord above the line of the first lumbar vertebra, which may also have some control over pregnancy and parturition. The experiments of Röhrig to which I have referred, show conclusively that stimulation of the upper end of the cord after it has been divided at the first lumbar vertebra (according to Goltz's method) still produces distinct muscular contraction in the uterus. This seems confirmatory of Th. Kömer's results,[2] according to whom the sympathetic nerves which leave the cord at the level of the eleventh and twelfth dorsal vertebræ go to the uterus. This nerve track was, therefore, not cut through in Goltz's experiments, and to isolate the uterus completely from all nervous connections we would have to destroy the cord from the tenth dorsal vertebra down to the sacrum, or cut through all nerves which run from the cord to the organ. We decided

[1] Ueber die Functionen des Lendenmarks des Hundes. Pflüger's Archiv, Bd. viii.

[2] Studien des Physiol. Instituts zu Breslau, Heft 3.

upon destruction of the cord, since intersection of the numerous nerve-fibres going to the uterus is attended with much manipulation and exposure of the abdominal organs, besides being a matter of considerable difficulty. The cord was accordingly destroyed by opening it at the tenth dorsal vertebra and running a white-hot copper wire down through the vertebral canal to the cauda equina. This procedure is not difficult and its immediate results do not injure the vital powers of the animal.

Schlesinger[1] has shown that the venous condition of the blood which is caused by temporary interruption of respiration acts as a stimulant to general contractions of the uterus. Röhrig[2] has confirmed this result, and shown at the same time that the contractions do not occur after the destruction of the cord. Spiegelberg[3] has shown that compression of the aorta, cutting off arterial blood-supply, also, in a few seconds produces contraction of the uterus. This has been confirmed by Röhrig and Schlesinger (*loc. cit.*).

Before destroying the cord in the manner stated, we tested the reaction of the uteri of the rabbits by temporary suspension of respiration, by compression of the aorta, and by electricity. After we had assured ourselves that contractions promptly occurred in from six to ten seconds after respiration was suspended (a rabbit breathes 40 in a minute), and in from ten to twenty-five seconds after compression of the aorta, and immediately following electrical stimulation, ergot was injected into a canula in the jugular vein in the form of 0.25 c.c. (4 minims) of ergotole dissolved in 1 c.c. (16 minims) of defibrinated blood from another rabbit or in the same quantity of normal salt solution. Uterine contractions began to pass gently over the organs four minutes after the injection, gradually becoming more intense. When 0.5 c.c. of ergotole was injected, or 1 c.c. (16 minims) of the fluid extract, the contractions of the uteri became tetanic in from three to five minutes after the injection, and continued to increase in violence for thirty minutes (average), then gradually decreased until they ceased altogether, in from fifty to sixty-three minutes after the first injection. When the contractions had thus passed off, and the uteri resumed a state of complete rest, the movements could be reproduced by a second jugular injection of ergotole. To reproduce the same effect the quantity as a rule had to be doubled; the tetanus then came on sooner, but lasted only twenty minutes, when the effects of the second injection ceased also.

When uterine tetanus is produced by ergot there is no relaxation between the spasms, as in the case of contractions produced by compression of the aorta or by suspension of respiration.

When the physiological effect of ergot had thus been established with a single injection of 4 minims of ergotole, and the organ had resumed a position of rest, the cord was destroyed from the tenth dorsal vertebra down to the cauda equina by means of a hot wire.

A second injection of ergotole (1 c.c. or 16 minims) into the jugular vein produces no contraction of the uterus. The result of a third injection of 32 minims (2 c.c.) of ergotole is also negative. Suspension of respiration and compression of the aorta for one minute each time now exert no effect upon the organ.

Electric stimulation, however, is promptly followed by energetic contractions. Injections into the jugular vein of three-per-cent. solutions of ammonia in defibrinated blood (1 c.c. of three-per-cent. solution in NH_3 in 2 c.c. defibrinated blood) are followed by strong uterine contractions.

The following is a tabulated account of one of the experiments:

October 27, 1890. A large, non-pregnant, albino rabbit is subjected to tracheotomy and curarized. A canula, with a rubber-tube attached to it, is tied into the cardiac end of the jugular vein, the other end of the rubber canula is filled with defibrinated rabbit's blood and clamped. Uterus exposed by abdominal section.

Time.	Kind of irritant or manipulation.	Result.
3.10 P. M.	....	Uterus at rest.
3.12	Faradic stimulation, positive pole on lumbar cord, negative on uterus, distance of coil 80 mm.	Strong contractions immediately.
3.15.30	Compression of aorta.	
3 16	" " "	Strong contractions.

4.50	Injection 1 c.c. 3 per. ct. solution of ammonia.	
4.51	....	Forcible antiperistalsis.
5.0	.....	The peristalsis produced by the ammonia lasted for 15 minutes, and continued for 5 minutes after the uterus was cut out of the body.

The foregoing table is an account of one of twelve successful experiments which convince us that (1) injections of from 0.25 c.c. to 0.5 c.c. of ergotole, or of 1 c.c. to 1.5 c.c. fluid extract of secale cornutum, will produce intense uterine contractions if inserted into the jugular vein when the cord is intact; (2) that when the cord is destroyed by a hot wire from the tenth dorsal vertebra downward, the above injections, and even double the quantity, have no effect; (3) that electric stimulation will cause prompt uterine contractions even after destruction of the cord; (4) that injections of 1 c.c. of a three-per-cent. solution of ammonium hydroxide will cause uterine contractions after destruction of the cord.

The conclusion is that ergot in producing contractions of the uterus acts primarily and essentially upon the lumbar cord, *i.e.*, its action in causing peristalsis of the uterus is centric, not peripheral.

In three of the experiments it was plainly shown that compression of the aorta and suspension of respiration do not cause uterine contractions after the cord is destroyed, therefore the action of the changes caused by these procedures are also centric and not peripheral. A three-per-cent. solution of ammonia was injected at the end of each experiment, when ergot no longer produced any contractions after cord destruction, and the prompt peristalsis occurring after the injection of ammonia under these conditions proves its action to be exerted directly upon the uterus and to be peripheral.

Does ergot cause increased intestinal peristalsis by direct local action or by exerting an influence upon the spinal cord?

This question could be conveniently solved together with the preceding one, as the same experimental method was applicable to both inquiries. Suffice it to say that in the twelve experiments upon the action of ergot on the uterus, careful observations were made of the peristalsis of the intestines. There is already much good evidence to show that ergot does cause increased intestinal peristalsis. Mr. Samuel A. Wright,[1] in a series of experiments, found very active peristalsis when ergot had been given by the mouth. Dr. Wernich[2] noticed violent peristaltic movements of the intestines following the injection of ergot. This was observed in rabbits whose abdomens were opened; in some cases, however, even through the uninjured abdominal walls. Wernich's statements have been confirmed by Handelin.[3]

Basch and Mayer[4] have stated that the dyspnœic condition of the blood caused by suspension of respiration stimulates not only uterine but also intestinal peristalsis. We are enabled to confirm this observation and to add that compression of the aorta also increases intestinal peristalsis. This compression was in two cases exerted upon the thoracic aorta to avoid direct mechanical irritation of the intestines. When the abdomen of a healthy rabbit is opened, the intestines being kept under normal salt solution, and allowed to remain undisturbed, peristaltic movements will cease in about from eight to ten minutes. If after this absence of motion is established, 0.5 c.c. of ergotole, or 1 c.c. of fluid extract of ergot, is injected with twice the volume (2 c.c.) of normal salt solution, there is at first no change observable in the intestines, but in from six to eight minutes (about the time the uterus shows signs of contraction) a fine quivering is plainly

[4] Quoted by Röhrig, Virchow's Archiv, Bd. lxxv.

noticeable along those parts of the ileum which are most easily visible.

In ten minutes distinct wavy contractions are seen to traverse the ileum and the colon. With a little care it can be proven that lumps of half-digested corn and cabbage are forced along the duodenum. By help of these masses of food it is not difficult to watch the progress of the peristalsis, which continues even after the motions of the uterus cease. In our experience the intestinal peristalsis kept up for forty-eight minutes, or nearly twenty minutes longer than the action of the uterus. When the peristalsis of the intestines caused by the first injection of ergot ceases, it can be reproduced by a second injection, which was generally allowed to run into the jugular vein from a eudiometer. If the cord was destroyed from the tenth dorsal vertebra down to the cauda equina, it was in no case possible to produce intestinal peristalsis by twice or even three times the quantity of ergot which had been previously used. It is justifiable, therefore, to conclude that ergot, in producing intestinal peristalsis, acts directly on the cord and only reflexly upon the intestines, its action in this case, too, being centric, not peripheral.

Contraction of arterioles under ergot.—We have made observations on this subject by microscopical examination of the frog's web and the rabbit's omentum and mesentery.

According to H. C. Wood, as early as 1827 M. Courhant advanced the opinion that ergot produces a spasm of the bloodvessels. In 1870 Dr. C. L. Holmes[1] published some observations on this point, and states that when the bloodvessels in the frog's web are watched under the microscope and the animal is poisoned with ergot, they can be seen to undergo a great contraction. A. Wernich[2] reports that when animals in which the arteries of the thigh, back, pia mater, etc., were laid bare, received full doses of ergot, these arteries could be distinctly seen to undergo decided contractions. Paul Vogt has confirmed these observations, also S. Kersch,[3] Boldt,[4] and Max Muller.[5] Boldt asserts that a wave-like peristalsis ran through the capillaries in ergotized animals. Peton, in 1878, observed in a rabbit's ear a complete change of color, from red to pale, under ergot, and proved that this anæmiation was independent of any influence exerted by the central nervous system. The following observation of Dr. Paul Vogt[6] is very interesting: He states that the dilated vessels of the ear of a rabbit whose cervical ganglion had been extirpated could not be made to contract by the hypodermic injection of ergot. P. Eberty's results[1] agree with those of Vogt. On the other hand, Dr. Holmes[2] asserts that after section of the sympathetic nerve and injection of the ergot, the vessels supplied by the divided nerve can be seen to contract, and Wernich[3] confirms this observation. Vogt's and Eberty's experiments, therefore, point to a centric origin of the contraction of the arteries, and those of Holmes and Wernich to a peripheric action. H. C. Wood[4] has especially investigated this subject, but chiefly with regard to the origin of the rise of arterial pressure, which will be most appropriately be considered under the next heading.

Although we examined the omentums of six of the rabbits on which we had made observations upon the uterus, we made six further experiments on this subject of arterial contraction under ergot. The omentum was constantly kept under a thin, slow current of warm normal salt solution.

As H. C. Wood says, that judging by the eye as to whether a vessel does or does not contract is very unreliable, we made use of the micrometer eyepiece and also of the so-called jury system. In this method the experimenter calls in the help of as many fellow-workers as are available, and directing them to watch with the micrometer a certain network of vessels in the omentum, without letting them see his injection of ergot into the jugular vein, asks them, "Tell me as soon as you notice any difference in the size of those vessels—do they grow larger or smaller?" Of ten observers assisting in this manner nine answered "smaller" within from two to three minutes after 0.5 c.c. of fluid extract of secale cornutum, or 0.25 c.c. of ergotole was injected. The tenth man said he was unable to tell, but thought the vessels remained about the same size.

It is but a fair conclusion in this case that ergot injected into the jugular vein produces contraction of the arterioles and capillaries in the omentum of rabbits with the spinal cord intact. The same study was made on the vessels of the ears of the rabbits, and especially on the web of the frog's foot, with the result that of all the ten observers the answer was the same, to the effect that a contraction had taken place when the ergot was allowed to run into the jugular vein from a eudiometer, but unseen by them. In animals, however, in which the spinal cord had been destroyed from the cervical region to the cauda, the vagi divided and artificial res-

[4] Phila. Med. Times, vol. iv.

piration set up, no contraction of the arterioles and capillaries was observable after ergot had been injected. Here the vote again stood 9 to 1 in favor of no reduction in the size of the vessels, the same man again declaring that he was not able to decide. This observation was also made upon the ears of the rabbits.

The conclusion is that ergot produces constriction of the arterioles and capillaries in the omentum and ear of rabbits and in the frog's web as long as the cord and the vagi are intact. These being destroyed constriction is no longer produced by the drug; its action in this case is centric, not peripheral.

The following study merits consideration in this connection: By means of a hot wire an inflammatory process was set up in one portion of the omentum. The congestion and infiltration extended around the point of irritation, making an area of inflamed tissue the size of a silver dollar. Whilst this area was under consideration it was steadily spreading and new capillaries seemed to grow out where three minutes before none had been visible. At this stage ergot was injected into the jugular vein of the animal (rabbit). Within three minutes the congestion and hyperæmia were visibly diminishing, and capillaries which we had observed developing, actually disappeared. We presume that there was no real new development of capillaries during the first hyperæmia, but that such as were already present but invisible because of their minute size became apparent from the general congestion, and disappeared again under the arterial contraction and consequent lessening of blood-supply to the capillaries caused by ergot.

Observations like those of Patrick Nicol and J. Mossop,[1] who noted with the ophthalmoscope the contraction of the retinal vessels after the exhibition of ergot in man, are very suggestive and convincing. I have made the same study of the retinæ of two epileptics at Bay View Asylum. The diminution of the calibre of the vessels under ergot was very apparent. It is not a reliable method, to judge of the effects of a drug in contracting the blood-vessels by observing the capillaries, because the size of these vessels is very variable at all times. Capillaries will not always have the same size in the same region of the body. One such minute vessel may appear so narrow that a single red blood-corpuscle passes through it with difficulty; at another time the same capillary will be wide enough to afford room for two or three such corpuscles to travel abreast. At certain moments, as when the access on the arterial side is blocked, or when blood for some reason ceases to flow into it, the capillary may be empty, its walls collapsed and in contact, and its lumen nearly abolished. At another time, when blood is flowing into it at high pressure, the capillary may be widely distended. It is, therefore, more accurate to watch the arterioles and larger capillaries only, and to base opinion chiefly upon micrometric measurements of the vessels, which is an easier method of observation.

(To be concluded.)

MEDICAL PROGRESS.

Treatment of Nasal Diphtheria.—In the *Revue Générale de Clinique et de Thérapeutique*, RAULIN recommends the following treatment for nasal diphtheria, both in adults and children. The membrane is not to be removed by direct manipulation, but is to be detached by means of antiseptic irrigation, while to prevent its re-formation, the surfaces upon which it is growing are to be covered by the following:

℞.—Lactic acid	. . . .	30 grains.
Carbolic acid	. . . .	45 "
Pure glycerin	. . . .	1 ounce.

After the disappearance of the exudate the catarrhal rhinitis which follows is best treated by means of astringent applications, and by washing out the nostrils with a spray composed of a solution of borate of sodium, or Dobell's solution may be used instead.

The Treatment of Strangulated Hernia by Belladonna and Atropine.—HAGEN, in the *Centralblatt für Chirurgie*, states that in twenty cases of strangulated hernia he has employed the following treatment: For several hours the hernial tumor is carefully treated by inunctions of an ointment made by adding 1 drachm of the extract of belladonna to 10 drachms of benzoated lard, and finally, under the skin, immediately over the tumor, is injected by means of a hypodermic syringe, $\frac{1}{150}$ grain of sulphate of atropine, which may be repeated if necessary. At the same time with these inunctions and injections taxis is employed, and in a certain number of cases Hagen found it unnecessary to resort to herniotomy. The employment of the belladonna and atropine renders the tumor more soft and yielding and furthers spontaneous reduction of tension. The reason for this treatment rests upon the statement of Schmiedeberg that belladonna and atropine in minute doses cause a contraction of the mesenteric vessels and an increased peristalsis of the intestinal walls.

Indications for Operation in Gastric Ulcer.—NISSEN (*St. Petersburger medicinische Wochenschrift*, No. 41, 1890) discusses the question of operative interference in cases of circular ulcer of the stomach, and relates a case from the clinic of Professor Unverricht. The patient was a man, aged forty-six years, who had had the usual signs of an ulcer of the stomach since July, 1887. His disease progressed with the usual symptoms of violent pain in the epigastrium, vomiting of blood, and progressive wasting, until September, 1889, when the symptoms pointed to perforation of the ulcer with commencing peritonitis. Professor Wahl thereupon opened the ab-

domen by an incision in the linea alba between the umbilicus and ensiform cartilage. There was no free gas in the peritoneal sac, and the stomach was easily made to present itself in the wound. Neither palpation nor inspection showed anything abnormal, and the serous coat was smooth and shining, although abnormally vascular. There was no peritonitis, however, and nothing to explain the clinical signs. The abdomen was closed, and the patient progressed fairly well for some days, but a month after the operation his temperature rose, and there was pain in the abdomen, culminating in collapse, from which he died. The clinical diagnosis was that of a perforating ulcer of the stomach with consecutive peritonitis. An examination was made and the left lobe of the liver was ascertained to be adherent to the stomach, and when the adhesions were broken, a small perforation was found in the anterior wall of the stomach. This hole had allowed the contents to escape into the peritoneal cavity. The stomach itself was hour-glass shaped, and had a large ulcer at its lesser curve extending down the anterior wall, where it had given way. In commenting upon this case Nissen points out that the indications for performing an operation, namely, perforation and commencing peritonitis, may not be fulfilled unless the lesser omentum be torn through and the posterior surface of the stomach explored with the finger. Nevertheless, should an ulcer be situated there, adhesions with the pancreas will often be found. A better means of diagnosing the position of ulcers seems essential to the successful performance of these operations.—*British Medical Journal*, January 3, 1891.

Treatment of Chancroid.—In *La Tribune Médicale*, CASTEL gives a summary of the present treatment of chanchroid. After stating that a large number of remedies have been brought forward during the last few years for the cure of this condition, he points out that iodoform is probably the best of these, and gives the following ways in which iodoform may be employed:

℞.—Iodoform . . . . 2 parts,
Powdered coffee . . . 1 part;

℞.—Iodoform . . . . 10 parts,
Carbolic acid . . . . 1 part;

℞.—Iodoform . . . . 2½ drachms,
Carbolic acid . . . 2 grains,
Essence of peppermint . 1 to 2 drops;

℞.—Iodoform . . . . ½ ounce,
Camphor . . . . 75 grains,
Essence of roses . . . 2 drops;

℞.—Iodoform . . . . 1 drachm,
Coumarine (principle found in Tonka bean) . . . } 15 grains;

℞.—Iodoform,
Powdered quinine,
Powdered benzoin,
Carbonate of magnesia (saturated with oil of eucalyptus), equal parts of each.

All of these methods mask, to a great extent, the disagreeable odor of the iodoform without in any way interfering with its favorable therapeutic effect. Castel also notes the following formulæ, which have been recommended in America, Germany, and France:

℞.—Salicylic acid . . . . 15 grains,
Powdered chalk or starch . 2 drachms;

℞.—Salicylic acid . . . . 20 grains,
Alcohol . . . . . 45 drops,
Benzoated lard . . . 2 ounces;

℞.—Salicylic acid . . . . 15 grains,
Alcohol . . . . . 2 ounces;

℞.—Salicylic acid . . . . 30 grains,
Alcohol . . . . . 3 ounces.

It is also stated by Castel that pyrogallic acid is a very useful application, and that Terrillon uses the following formula:

℞.—Starch . . . . . 1½ ounces.
Vaseline . . . . . 6 "
Pyrogallic acid . . . 1½ "

The salicylic and pyrogallic acid prescriptions are, of course, very much more powerful stimulants and irritants of the sore than are those of iodoform which have just been given.

The Treatment of Urticaria.—QUINQUAND recommends the following treatment for this troublesome affection: Internally he prescribes the alkalies, the arsenite of sodium, and naphthol; and when the itching becomes intolerable, he relieves it by the following lotion:

℞.—Boric acid . . . . 1½ ounces.
Chloral . . . . . 1 drachm.
Water . . . . . 6 ounces.

The following powder is also of value:

℞.—Powdered starch . . . 1½ ounces.
Oxide of zinc . . . . 3 drachms.
Salicylic acid . . . . 1 drachm.

External Application of Aristol.—The *American Journal of Pharmacy* quotes the following formula for an aristol paste:

℞.—Aristol . . . . . 3 parts.
Alcohol . . . . . 5 "
Ether . . . . . 5 "
Soft soap . . . . 30 " —M.

Soft paraffin is also a good vehicle, and a mixture of equal parts of lanolin and petrolatum has been recommended for the same purpose.

Sulphur in the Treatment of Smallpox.—According to the Paris correspondent of the *Archives of Pediatrics*, DR. ISCAR prescribes sulphur in cases of smallpox, and claims much success. He thinks that it is eliminated by the skin and that this accounts for the good effects. For children he uses the following formula:

℞.—Washed sulphur . . . 2½ drachms.
Glycerin } of each 15 "
Orange-flower water }
Syrup . . . . . 7½ " —M.
Dose, one teaspoonful every hour.

OPPOSITION OF HOMŒOPATHS AND ECLECTICS TO THE MEDICAL EXAMINERS' BILL.

THE MEDICAL NEWS recently published and made editorial comment upon the Bill prepared by the Medical Society of the State of Pennsylvania to establish a State Board of Medical Examiners, similar to those existing in Minnesota, Virginia, and other States. It was then said that the Bill was a just and fair one to the State, the profession, the candidate desiring license to practise, and to those practitioners believing in special dogmas. An opposition to a State Board of Examiners has been developed, however, on the part of the homœopaths and eclectics, who, in combination, have prepared and introduced a Bill into the House of Representatives at Harrisburg, entitled "An Act to establish a State Board of Medical Education," etc. The text of this Bill is published in the present issue of this journal, in order that its provisions may be carefully studied. Its fundamental principle is that the Board shall regulate the extent and character of the preliminary education of intending medical students, and fix the character and time of instruction given in medical schools. It shall issue, without examination, certificates to all graduates of the medical schools of Pennsylvania, which must conform to the standard set by the Board; and shall examine graduates of schools situated outside of Pennsylvania which do not appear to conform to the said standard.

The bill introduced by the homœopathists and eclectics, however, does not seem to be carefully worded or justly conceived. There is no provision to assure the public that the graduating examination in the medical colleges shall be a sufficiently rigid one. "The methods of instruction employed and the facilities for teaching" are to be inspected (see Section 6); but after such inspection the colleges may graduate the most ignorant persons after secret examinations of a most trivial kind. The preliminary examination is also to be regulated as to extent and character, but no attempt is made to see that it is faithfully conducted. The casual reader will see that no protection against medical ignorance and incompetence would be given by such a law. At the present time there are colleges in all parts of the world which have good methods and excellent facilities, but the graduates need not, and often do not, attain much proficiency, because the final examination is too lax.

The defective protection afforded by the bill shows that it is far inferior to the bill to "Establish a State Board of Examiners," published in THE MEDICAL NEWS, January 10, 1891. In addition, the evident intentional injustice of the homœopathic and eclectic Bill to Establish a Board of Medical Education makes its defeat an imperative necessity on the part of the regular medical profession. It is drawn (see Section 1) in such a manner that the appointing Governor must always put the regular profession in a perpetual minority. There must forever be out of the 9 members 6 irregular practitioners upon the Board, viz., 3 homœopaths and 3 eclectics. In other words, the homœopathic and eclectic physicians of Pennsylvania, who number about 1000, are to have police supervision over and power to annul the charters (see Section 8) of the five regular medical colleges of the State, which represent nearly 7000 resident practitioners of rational medicine, and this in face of the fact that the irregular physicians have but a single college in the Commonwealth. Other defects in the law are that professors in medical schools may be appointed on the Board, and that no two members shall be residents of the same county. Consequently, the sole member from Philadelphia County would probably always be a member of the faculty of one of the medical schools. The possibility of just educa-

tional supervision under such circumstances is very doubtful.

It is astonishing that the homœopathic physicians who have long expressed a desire for a higher standard of education, should have combined with the eclectics to defeat the non-sectarian and carefully-drawn bill to create a Board of Medical Examiners. This bill provides that the Governor shall appoint three eclectics from nominees made by the Eclectic Medical Society of Pennsylvania.

We would urge every member of the profession in this State to write to his representatives at Harrisburg, insisting that the basis of representation shall be as fairly proportioned in this act as in any other measure which may become a law. Until we have proper methods of protecting our fellow-citizens and ourselves the profession of Pennsylvania must always be under a cloud of illiteracy and quackery.

CORRESPONDENCE.

PARIS.

Koch's Remedy in Paris.

KOCH'S lymph has now been experimented with in Paris for more than a month. The observations have been made upon medical, dermatological, and surgical cases. In medical cases, such as pulmonary tuberculosis, the results have not been as favorable as was expected. In cutaneous tuberculosis, improvement or changes in the prëexisting condition have certainly been brought about, and seem to indicate that the remedy will prove to be of some value in such diseases. In surgical tuberculosis the results have not been encouraging, but we shall have to wait for months before a positive opinion can be expressed as to the value of the remedy in all classes of tubercular cases.

As soon as the precious lymph was received it was placed in the hands of one of our most careful scientific men, Professor Cornil, the cases treated being watched by his very careful assistants, Professor Chantemesse and Dr. Vidal. Dr. Cornil began his inoculations in the latter part of November. The first patient to receive the treatment was a very extensive case of lupus, covering the whole face and the left arm, forearm, and hand. The often-described action of the remedy was very marked in this patient. Six hours after the injection she began to cough, and it was found that she had tuberculous lesions in the upper portion of her lungs. The second case was one of tubercular epididymitis; the right spermatic cord was about one-half inch thick, while in the left epididymis there was an almost imperceptible nodule. Under the influence of the remedy the right epididymis enlarged and the nodule in the left epididymis became of the size of a hazelnut. No marked general symptoms occurred in this case after the first injection, but after the second injection the patient complained of severe renal pain, and was found to be suffering from hæmaturia and albuminuria, the albumin and blood being present for several days. A third case of lupus was also injected, and while no general symptoms appeared, the local symptoms were pronounced.

Professor Cornil has found that reaction is always produced by the lymph in cases of undoubted tuberculosis. Certain irregularities, however, have been observed, some patients having a very slight rise of temperature, although there was a very marked local reaction in the lung. In some cases both the local and general reaction were marked, while in others the general reaction was marked, although the local was very feeble. The general symptoms differ acccording to the quantity of liquid injected and also the idiosyncrasy of the patient. In a case of tubercular arthritis of the elbow of twenty years' duration which was thought to be cured, five milligrammes of the lymph brought on no reaction. In another case of old tubercular arthritis, no reaction was observed. Professor Cornil concludes that in old tubercular arthritis which has reached the fibrous stage, no reaction will occur. On the contrary, the reaction is much more intense when we have to deal with a rapidly developing recent tuberculosis.

As regards the sensitiveness to the drug, Dr. Cornil presented a patient suffering from tuberculous lesions of the skin, cold abscesses, tuberculous disease of the elbow and wrist, necrosis of the malar bone and pulmonary tuberculosis in the first stage. After the injection, the patient had a red and painful swelling on one finger. It is probable that this tubercular lesion was merely made evident by the injection.

A child about thirteen years old, who had had pulmonary tuberculosis for only a month presented, when admitted, a few dry crackling râles under the left clavicle and also slight dulness on percussion. At the first injection the physical signs were greatly increased.

When one has to deal with latent tuberculosis, the injections increase the physical signs, and render distinct symptoms which were previously doubtful.

All the organs of the body are liable to be affected by Koch's lymph, and two of the lupus patients who were injected, presented marked hæmaturia. The urine, which was of a rose color on the day following the injection, became brown for four or five days after, and contained albumin. On microscopical examination besides free blood-corpuscles, hyaline casts filled with deformed blood-corpuscles, were found.

Three hypotheses are to be considered as an explanation of these phenomena, first, tubercular granulations may have been present in the kidney; second, there may have been a slight nephritis with an epithelial degeneration or an interstitial periglomerulus lesion; or third, these patients may have had amyloid degeneration of the kidneys. As soon as albumin is detected in the urine of a patient treated by these injections, no further injections are given until the urine has returned to normal. Strange to say, in a case of advanced phthisis, with diabetes and a double calculous pyelonephritis, injections instead of bringing on hæmaturia, have shown no action on the kidney—the quantity of pus in the urine has even diminished.

Five nephritic patients who presented skin-lesions were also inoculated, for the purpose of ascertaining the

action of the remedy on them, each receiving one milligramme, but none of them presented any reaction.

As regards temperature, Professor Cornil and Dr. Vidal have observed that the rise is not confined to one day, but may return on several successive days. In one case the temperature reached its maximum in from eight to twelve hours, it then rapidly fell within the four following hours to nearly normal, and in twelve hours again rose to the former height. In another case, one of lupus, the temperature rose daily for three days.

A third case, a girl aged seven years, who received one-half milligramme of the lymph, presented no general reaction immediately after the injection, but between the second and fourth days the temperature rose and varied between 100° F. and 104°. This case shows that one cannot safely make an injection every day.

Dr. Henague has also made examinations of the amount of oxyhæmoglobin in inoculated patients. Out of twenty-two patients he found that in thirteen the oxyhæmoglobin was diminished. In three there was first a diminution then an increase. In three an increase, and in three no variations were observed. A diminution in the quantity of oxyhæmoglobin seems to be the rule.

It must be stated, that the opinion arrived at now, after more than a month's treatment, is that in most of the patients suffering from cutaneous tuberculosis the symptoms have been *ameliorated* but not *cured*.

One must be very careful in treating lupus with the lymph, for in the majority of cases treated here, the patients presented physical signs of tuberculosis of the lungs, when no trace of the disease could be found before the inoculation.

In surgical tuberculosis the results are variable, in some cases the symptoms are ameliorated, in others aggravated. As a rule, whenever the lesion is deeply situated swelling and pain are annoying symptoms and will require the interference of the surgeon, while if the lesion is in communication with the surface by a fistulous opening, no danger need be feared.

Injections of the lymph for laryngeal tuberculosis have been made at several hospitals, the conclusion being, that the method may be of service, but must not be used except by a specialist, who should be ready to operate if stenosis of the larynx occurs.

In a few words the opinion in Paris is that the curability of phthisis by Koch's lymph is very doubtful.

NEWS ITEMS.

State Board of Medical Education.—The following act has been presented to the Legislature of Pennsylvania by the homœopathists and eclectics:

AN ACT

To Establish a State Board of Medical Education, to Define the Powers and Duties of such Board, and to Make an Appropriation therefor.

SECTION 1. Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania in General Assembly met, and it is hereby enacted by the authority of the same: That within three months after the passage of this Act, the Governor shall appoint, by and with the advice and consent of the Senate, a State Board of Medical Education, consisting of nine members, physicians in good standing, citizens of this Commonwealth, three of whom shall serve for two years, three for four years, and three for six years; and thereafter, biennially, there shall be appointed in the same manner three members of the said Board, one from each school of practice, as provided in this Section, to serve for six years in the place of those whose term shall have expired. They shall be graduates of some legally-chartered medical college, or university having the power to confer medical degrees, who shall have practised medicine or surgery for a period of not less than five years. Provided: That in the appointment of said Board the members shall be chosen equally from lists of names, each list containing the names of ten registered physicians submitted by the State Medical Societies of the Commonwealth of Pennsylvania, to the intent that the three systems of medicine—*i. e.*, homœopathic, allopathic, and eclectic—be equally represented thereon; and provided, further: That no two members shall be residents of the same county. In default of the submission of such lists, the appointments shall be made by the Governor at his discretion from among the registered physicians of the Commonwealth having the qualifications specified in this section.

Every appointment to fill a vacancy, or vacancies, in the said Board shall be for the unexpired term, and the said vacancy, or vacancies, shall be filled by the Governor within sixty days after notification of the same, in accordance with the provisions hereinbefore stated; and he shall have power to remove any member of said Board for criminal, scandalous, or dishonorable conduct.

SECT. 2. The said Board shall be known by the name and style of "The State Board of Medical Education of the Commonwealth of Pennsylvania," and shall have a common seal, and may make and adopt all necessary rules and regulations and by-laws, not inconsistent with the Constitution and laws of this Commonwealth, or of the United States, and shall have power to locate and maintain an office for the transaction of its business.

Five members of said Board shall constitute a quorum.

SECT. 3. The Board shall meet at least twice each year, at such times and places as they may determine upon after the first meeting, which shall be held within sixty days after their appointment at such time and place as the Governor may direct, at which time, and annually thereafter, they shall organize by the election from their own number of a President, and a Secretary who shall also act as Treasurer. Provided: That the President and Secretary are not of the same school of medicine.

SECT. 4. No member of the Board, except the Secretary, shall, as such, receive any salary; but the actual travelling and other expenses of any member, while engaged in the actual duties of the Board, shall be allowed and paid on presentation to, and approval by, the Auditor-General, of an itemized account with vouchers annexed.

SECT. 5. It shall be the duty of said Board of Medical Education to make all regulations as to the extent and character of the preliminary education which shall be required of all students of medicine, and notify the dean

of each medical college of the same. Any change in the standard required must be announced by the Board at least one year prior to going into effect.

SECT. 6. The Board of Medical Education shall fix the minimum curriculum and length of course of studies requisite to graduation. Provided: That the course shall not be less than four years, which shall include three annual terms of lectures. The Board shall delegate one or more of their number, who, from time to time, shall make an inspection of the methods of instruction employed, and the facilities for teaching, in each such medical college, and annually report the same to the Board.

SECT. 7. It shall be the duty of the Board to issue, under seal, to each graduate of such medical colleges as upon evidence of the dean and the secretary, or registrar of the same, shall have conformed to the requirements of the Board as herein before provided, a certificate duly setting forth such facts. Such certificate shall entitle said graduate to register in any county of the State, in accordance with the act entitled, "An Act to Provide for the Registration of all Practitioners of Medicine and Surgery," approved June 8, A D. 1881.

The fee for such certificate shall not exceed two dollars.

A similar certificate may be granted to graduates of medical colleges of other States, who may desire to practise medicine or surgery in this State, provided that such colleges stand approved by the Board of Medical Education of this Commonwealth as maintaining a standard in every respect, preliminary and final, equal to that required of the medical colleges within this Commonwealth.

The fee for such certificate shall not exceed five dollars.

Graduates of colleges having a lower standard than that required by the Board of Medical Education of this Commonwealth, may receive the certificate of the Board upon a satisfactory examination before said Board. Such examination shall be in writing, and shall apply to the preliminary education, as well as the medical knowledge of the applicant. Provided, That all questions pertaining to materia medica, and therapeutics, shall be propounded and acted upon, by members of the Board of the same school of medicine with the applicant.

The fee for each such examination shall be twenty dollars.

All examination papers shall be kept upon file, and open to inspection, for a period of two years in the office of the Board.

SECT. 8. If upon investigation the Board of Medical Education discovers, that after the passage of this act, any medical college within this Commonwealth, has granted the degree of doctor of medicine to any person, or persons, deficient in respect to either of the aforementioned preliminary or final educational requirements, or that any medical college within this Commonwealth, has conferred the degree of doctor of medicine upon any person or persons, without having passed a final examination, it shall he the duty of the Board to notify the dean of said college of such fact, and proceed against such college for such infringement of the law. The penalty for a first offence shall be a fine of not less than two hundred nor more than one thousand dollars. For a second offence, a fine of one thousand dollars shall be imposed, and the certificate of the Board of Medical Education shall be withheld from future graduates of said college, except upon examination before said Board, as provided in Section 7 of this Act. In case of conviction for a third offence, the charter of such college shall be annulled.

SECT. 9. The Board of Medical Education is hereby authorized and empowered, to bring suit for the collection of such fines, and imposition of such penalties, in the courts of the county wherein such college may be located.

All fees and fines collected by said Board shall be paid to the State Treasurer.

SECT. 10. After the first day of June, 1892, no physician shall be permitted to register in any county of this Commonwealth except upon presentation of a certificate as provided for in Section 7 of this Act whereupon, he he or she shall be entitled, upon the payment of one dollar to be duly registered in the office of the Prothonotary of the Court of Common Pleas in the said county; and any person violating the provisions of this Act shall be guilty of a misdemeanor, and, upon conviction thereof in the Court of Quarter Sessions of the county where the offence shall have been committed shall pay a fine of not more than fifty, nor more than five hundred dollars for each offence.

SECT. 11. Nothing in this Act shall apply to commissioned medical officers of the United States army or navy or of the United States Marine-Hospital Service, nor to the member of the house or resident staff of any legally chartered medical college or university or hospital during his or her term of service therein, nor to physicians of other States meeting duly registered physicians of this State in consultation, nor to those practising dentistry exclusively, nor in any manner whatever prevent or interfere with the dispensing and sale of medicines or medical appliances by apothecaries or pharmacists, and nothing in this Act shall be construed to prohibit the practice of medicine and surgery within this Commonwealth by any practitioner who shall have been duly registered before the first day of February, 1892, according to the terms of this Act, entitled "An Act to provide for the Registration of all Practitioners in Medicine and Surgery," avproved the 8th of June, Anno Domini, 1881.

SECT. 12. The Board shall make to the Governor, on or before the first day of December of each year, a full report of the work of the Board for the year.

SECT. 13. For the purposes of this Act, the words "practice of medicine or surgery," shall mean to treat, or attend, any person for money, gift, or reward.

SECT. 14. The sum of two thousand dollars is hereby appropriated to meet the necessary and legitimate expenses of the said Board.

SECT. 15. Section 4 of an Act entitled "An Act to provide for the Registration of all practitioners of Medicine and Surgery," approved the eighth day of June, Anno Domini 1881, is hereby repealed.

Obituary.—Edward Bellamy, F.R.C.S., senior surgeon to Charing Cross Hospital, London, died January 4, 1891, of acute pneumonia, at the age of forty-eight years.

OLD AGE AS A FACTOR IN SURGERY.

BY N. F. GRAHAM, M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF HOWARD UNIVERSITY, WASHINGTON, D C.

MANY surgeons have always clung to the opinion that in old age there is little power to recover from surgical diseases, and when we consider the changes which have taken place in the tissues and organs of persons advanced in life, it is not to be wondered at that such an idea should prevail. The laity have always believed, and still believe, that old age is a grave barrier to recovery from either injury or disease.

Certain atrophic and degenerative changes take place in old age which affect glands, muscles, and other soft parts. Cells become smaller without change of structure. The spleen and lymphatic glands become greatly diminished in size, and the same is true of the villi and glands in the digestive tract. At a still later period of life senile changes commence in which there are fatty degeneration and calcareous deposits. The fatty changes affect muscles, nerves, vessels and glands; the calcareous deposits are found in muscles, ligaments, cartilages, heart, and bloodvessels. The result of these atrophic and degenerative changes is impairment of all the functions of the body. The cellular elements, though diminished in size, still retain their physiological characteristics, and so, when the tissues become inflamed, the same changes take place in the cells and bloodvessels as in younger subjects.

The cellular structures of the old will return as certainly, though not as speedily, to the embryonic state when a part is in a state of inflammation, as in the young or middle-aged. This affords the best explanation of the facility, and very often the certainty, with which wounds and injuries are repaired in old persons.

The readiness with which fractures and grave injuries in the aged are repaired is every day becoming more and more manifest, so much so that our preconceived ideas are changing, and age can no longer be adduced as a strong reason against the hopeful and careful treatment of wounds, ulcers, fractures, and other surgical diseases, with fair chances for good results.

Recovery from serious illnesses as well as from injuries in old people is very interesting. It seems strange, when the other nutritive forces are failing, or already gone, that those connected with repair should remain in so good a condition. The explanation must be found in the fact that the cellular elements retain their normal physiological condition (except as to size) as long as the individual lives; although, for successful results, the blood and bloodvessels need to be in, at least, fair condition.

Certain conditions of the body exist in these cases which give them some advantages over the young. They possess a lower and slower excitability. They are not so liable to hæmorrhages—primary or secondary—or to acute inflammatory troubles. Their nervous systems have undergone changes which make sensation more obtuse, and, therefore, they are not as subject to acute nervous affections, such as tetanus and painful spasm of the muscles, as are younger subjects.

On the other hand, there is a strong tendency to diseases of the heart and vessels, so that shock is not so well borne, and as a consequence there is feeble or slow reaction. This fact has, very naturally, prejudiced surgeons against undertaking operations in old persons; but if, on examination, the vital organs—the heart and nerves—are found sound, with a firm, regular pulse, there need be no hesitation in operating, as, under such circumstances, the chances for success are good.

After the age of seventy years the number of persons who require operations is not very large, but to those who do a refusal is often given by the surgeon and their friends on the plea of age. Provided that the patient is in fair general health, with a hereditary tendency to long life, mere age is not a good reason for withholding treatment either with the view to prolonging life, or for the relief of acute suffering.

The following cases, some of which came under my own observation and treatment, and others of which were selected from various sources, show wonderful recuperative powers in very old men and women:

CASE I.—J. S., a negro, aged ninety-two years, came under my care in the Freedmen's Hospital in the winter of 1882, suffering from gangrene of the left foot and leg, the result of senile changes in the arteries. The "line" was irregular, extending around the limb and forming a triangle, the apex reaching within four inches of the lower edge of the patella, the base occupying the lower part of the

belly of the calf. The granulations were abundant and healthy in the large groove which separated the dead from the living tissues.

On January 5th, I amputated the leg three inches below the knee by the double-flap operation. The only bleeding was free oozing from the capillaries, and there were no vessels which required ligatures. The flaps were brought snugly together, stitched, and the stump dressed with iodoform-gauze. Healing took place, mainly, by first intention, and the man was able to be about on crutches at the end of six weeks.

CASE II.—S. L., a white male, aged eighty-seven years, with an axe-wound of the face, cutting directly through the centre of the bridge of the nose, and with a downward inclination deep into the maxilla, and opening into the mouth through the right side, making a cut five inches in length. The divided portion of the nose, with the other soft parts, fell over the mouth and chin. When I reached the patient he was unconscious from shock and loss of blood, with two small arteries—one on each side of the nose—spurting. I ligatured the vessels, cleaned the wound, and adjusted the detached part of the nose and face, placing the first stitch in the centre of the bridge, and five others on each side; applied narrow adhesive-plaster strips between the stitches, and covered the whole with a moist cloth—the only dressing at hand. The wound healed readily, and the man was able to be out of bed in four days, and out of the house in ten.

CASE III.—Mr. H. L., a large, strongly-built man, eighty-eight years of age, noticed in December, 1887, a small pulsating tumor in the left popliteal space, which rapidly increased until it reached the size of a small orange, when it suddenly became very painful. He also suffered from intense pain in the toes, foot, ankle, and leg of the same side. At this juncture—early in March, 1888—he consulted a good surgeon, who advised him to wear an elastic bandage or snug knee-cap, which he did without much benefit.

I saw him about the middle of March, when there was no abatement of the pain, which prevented sleep. The foot as far as the instep was white, and there were discolored patches on all the toes. The first stage of gangrene was clearly marked. His great age was discouraging, considering the complicated nature of the case. I flexed the leg on the thigh at an angle of forty-five degrees, wrapped the foot and ankle in a liberal amount of cotton-wool, and kept the patient well under the influence of morphine. This, with friction of the leg and foot twice daily, for an hour at a time, with good food and stimulants, was the only treatment. In about five weeks the aneurism ceased to pulsate, the gangrene remained limited to a small portion of the great and second toes, and in two months he was able to go about on crutches, which he has now discarded, though he is still lame. The aneurism is completely cured, and the loss of substance from gangrene is scarcely noticeable.

CASE IV.—In December, 1884, Mrs. S., aged ninety-one years, came under my care with a fracture of the bones of the forearm near the wrist, the result of a fall. I adjusted the fracture and applied two well-padded, straight splints. Good union took place in six weeks, with the result that the arm was as useful as before the fracture.

The same patient had had a fracture through the neck of the left femur, at the age of eighty-one years, from which she recovered in ten weeks with firm union and a useful limb, though with one and one-half inches shortening. The only treatment for the fractured femur was the application of sand-bags, without extension.

CASE V.—In November, 1886, I treated Miss B., aged seventy-six years, for fracture of the lower end of the right radius, by adjusting the fracture and placing a pistol-shaped splint on the limb. At the end of six weeks union was good, and in eight weeks she could use the hand as well as ever. Five years previously to the date of the fracture, I assisted in removing her right breast for cancer, from which she made rapid recovery, though in 1886 the disease again developed in the scar and axillary glands, and has since proved fatal.

CASE VI.—Mr. F., a robust man, seventy-five years old, came under my care in August, 1890, with a large carbuncle on the back of the neck, extending from just below the occipital prominence to the fifth cervical vertebra and on both sides to the ears. The size of the open slough was three by four inches. Under ordinary treatment, with the addition of injecting into the mass, twice daily, from two drachms to half an ounce of peroxide of hydrogen, which was first done by Dr. Balloch during my absence from the city, and continued by me after my return, the patient made an excellent recovery, and was out in six weeks.

CASE VII.—In November, 1885, I operated on J. G., aged seventy-four years, for epithelioma of the lower lip, and removed a wedge shaped piece, the base of which extended from the angle of the mouth to the centre of the lip and the apex to near the symphysis. I brought the edges together with three pins and a stitch through the upper part of the lip. Union took place by first intention. There is no deformity and no signs of a return of the disease.

CASE VIII.—R. S., aged eighty years, came under my care in July, 1888, for epithelioma of the lower lip, which had destroyed two-thirds of the margin of the lip, and had extended as an irregular ulcer to the chin. I removed a V-shaped piece, including the diseased portion, brought the cut edges together with pins, and enlarged the mouth by an incision an inch in length on the sound side, stitching the mucous membrane to the skin. Union took place by first intention, leaving but a small notch at the angle of the lips, in spite of the fact that he was a hard drinker. The man is still robust and has no evidences of a return of the disease.

The *Dublin Medical Press*, August, 1864, reports the case of May C., aged one hundred and one years, whose right hand was amputated for cancer on April 10, 1864. Healing was mainly by first intention, and repair was complete in one month.

In the same issue of that journal is reported the

case of Miss A., aged eighty-four years, suffering from scirrhus of the left breast. The entire gland was removed, and recovery took place with no bad symptoms.

The *Bristol Medical Journal*, March, 1886, reports the case of a man, aged eighty-nine years, who recovered with good use of the knee, after a severe fracture of the patella; and in the same journal is reported a similar accident, with equally good results, in a man aged seventy-two years.

The *British Medical Journal*, June, 1883, reports a case of operation for strangulated femoral hernia in a woman aged eighty-eight years. Recovery was rapid, though she was so feeble that her relatives protested against the operation, and, as they said, wished the old lady to die in peace. There is also reported in this journal a case of fracture of the right femur at the age of eighty years, with good recovery; and a man, aged ninety-two years, with fracture of the bones of the forearm, good union taking place in the ordinary time, with fair use of the hand; also the case of Miss S., who died at the age of one hundred and four years. She broke the neck of her femur at the age of one hundred and one years, and, though union failed to take place, she lived three years afterward, and went about comfortably on crutches.

A Hindoo, aged ninety-six years, whose case is reported in the *Medical Times and Gazette*, 1867, p. 607, suffered from a fracture of the left tibia and fibula above the ankle, the foot being bruised and excoriated. The fracture occurred on September 11th, when it was dressed in ordinary side splints. On September 29th he could bear his weight on the leg, and on October 11th he walked out of the hospital perfectly well.

Gowers, in *The Lancet*, 1887, vol. ii. p. 85, reports two cases of epithelioma. One was in a man aged seventy-eight years, the left cheek being covered by a sore seven inches in circumference, the removal of which was followed by recovery. The other was in a woman aged eighty-two years, requiring amputation of the finger for the disease. Union by the first intention took place.

In the same journal Dr. Hutchinson reports the case of a man ninety years old, who suffered from gangrene of the hand and forearm. The line of demarcation formed and the gangrenous mass separated. Amputation of forearm; stump healed well.

Dr. Ferguson reports in the same number of *The Lancet* a case of melanotic sarcoma, in a man aged seventy-five years. The mass was situated at the apex of Scarpa's triangle, and was removed with difficulty, exposing in the operation the femoral vessels. Erysipelas supervened, but the patient made a good recovery.

In *The Medical Journal and Review*, 1849, is reported the case of a negro known to be one hundred and two years of age, and believed to be older, who made a good recovery after amputation of the right leg. Dr. Thomas Annandale, in the same journal, reports twelve cases of an average age of seventy-two years, on whom he operated at various times. Five of the operations were for cancer, one was resection of the elbow; two were amputations of the arm; two for large fatty tumors; and one in a man aged seventy-eight years, for strangulated hernia. He also operated for stone in the bladder on a man seventy-four years old. In all of these cases there was recovery followed with good results.

As a general rule, old people tolerate pain better than do the young. Owing to the changes which have taken place in their nervous systems their sensibilities are obtuse, and, therefore, they complain less, while owing to the same condition of the nervous system, combined with other senile changes in the heart and other organs, shock is more severe and not so quickly rallied from. They endure operations for pathological conditions, such as the removal of tumors, cancers, etc., remarkably well, because they have in some degree acquired a tolerance to the gradual change and tissue-metamorphosis which render operations necessary.

Their recovery from wounds is not so rapid, for the reason that the cells and intermediate substances are more rigid, and the softening process which changes the tissues when in a state of inflammation to a condition suitable for repair is slower. In the old, tissue-genesis predominates over suppuration. The growth of morbid tissue goes on at a more moderate pace; cell-division is not so rapid or general as in the young, and, as a consequence, there is less waste from pathological conditions. We can also see how the processes of repair can take place more readily when there is but little excitability of the tissues, a condition often found in the aged, and which may also partly explain their recuperative powers. It is, however, but reasonable to conclude that they are much less able to stand the shock of injuries and operations than are persons in the prime of life, owing to the senile changes which have affected every organ of the body, and, particularly, the heart, bloodvessels, and nervous system. Hence in shock lies the greatest danger to the aged, and if the patient rallies the prognosis, so far as repair is concerned, may be considered good.

REMOVAL OF RENAL CALCULI FROM THE MUSCLES OF THE LEFT LUMBAR REGION.

BY MARIE B. WERNER, M.D.,
OF PHILADELPHIA.

MISS G., aged thirty-two years, gives the following history: As long as she can remember she has suffered from recurring pains in her left side radiating down toward the groin.

She had scarlatina at the age of seven years, followed by so-called remittent fever. Some swelling of both the hands and feet was noticed at that time, and the urine was high-colored and deposited a brick-dust sediment; no chemical or microscopical examination was made.

At the age of ten years she had a slight attack of measles, followed by good recovery.

During the winter of 1876–77 she had an attack of so-called intermittent fever associated with pains in the back and œdema of feet, hands, and face. The urine was heavily loaded with a brownish-red sediment; no chemical or microscopical examination was made. Recovered in March, 1877.

In 1882 the patient suffered from pain in her abdomen and back, radiating to the groin and thigh. This was pronounced rheumatism. She again became dropsical, and her urine was thick, dark, and of a peculiar odor. Patient remembers a discharge of "blood and matter" from the urethra. There were also high temperature and rigors. After two months' continued pain a lump formed in the left lumbar region.

Home remedies failing, her physician was again summoned, who pronounced the swelling a scrofulous abscess. This was twice lanced. The openings partly closed, but four sinuses remained, through which the contents forced their way.

An attack of pneumonia in the spring of 1889 necessitated long-continued rest in bed, thus interfering with proper drainage. During this time two of the four sinuses closed, and a new one formed just above the crest of the ilium.

When the patient was first seen by Dr. Calista V. Luther and myself, September 19, 1889, she was emaciated and weak, had an anxious expression, and every movement was an unconscious study to immobilize the affected side. Inspection showed two cicatrices and two open sinuses occupying a space of about three inches square, one inch to the median line of the first three lumbar vertebræ, and a third sinus above the crest of the left ilium.

A probe, passed for two inches into one sinus in the back toward the crest of the ilium, met a hard, roughened substance, suggesting necrosed bone. The sinus opening near the crest of the ilium admitted the probe a distance of six inches upward and somewhat backward, and no resistance was felt. A stream of water injected through the longest sinus escaped from the shorter ones in the back.

Dr. Luther examined the urine and found no albumin or pus.

We decided that an exploratory incision was the only proper course of treatment.

On October 26th, the patient being chloroformed, assisted by Drs. Joseph Price, Kynett, and Luther, I made an incision through the two sinuses in the back, and found two calculi, the larger an exact cast of the pelvis of the kidney and with a prolongation which evidently had extended into the ureter. The base of this calculus was marked by roughened prominences, possibly due to extension into the renal tubules. The other calculus was the size of a coffee-bean. (See Figure.)

The long sinus was then opened and thoroughly scraped, making a large, T-shaped wound. There was but a thin wall between the cavity containing the stone and the kidney, which was felt through the relaxed abdominal walls.

An exploring needle was plunged into the kidney in three directions to ascertain if there were other calculi, but with negative results. The wound, thoroughly disinfected with bichloride solution, was

then packed with bichloride gauze, over which was placed a bandage, and the patient was put to bed. Thirty-six hours later the lips of the wound were approximated with adhesive plaster.

The long incision, about eight inches in length, healed very kindly; the shorter one, however, refused to close, as it was near the cicatricial tissue left by the two closed sinuses. All stimulation proved of no avail.

December 12. Dr. Luther and I concluded to remove as much as possible of the fibrous tissue and draw the flaps together with sutures. This was done, and some strands of chromicized gut were laid in the bottom of the wound, a dry compress bandage of bichloride gauze held in place by broad adhesive strips was applied and left undisturbed for five days. On removing the strips there were considerable odor and moisture, probably owing to the catgut, which seemed to have acted more as an irritant than a drain. Deep union seemed good, and the surface appeared healthy. Dressed with a ten-per-cent. solution of sulphurous acid.

24th. Only a small space in the triangle was unhealed. This has remained a small fistulous track, and from it the patient believes she detects at times an escape of gas.

Her general condition improved markedly, and the opening is only annoying by its presence.

The calculi were seen by Professor Leffmann, who, after examining the smaller one chemically and microscopically, reports the following:

"The fragment of calculus which you sent consists principally of calcium phosphate mixed with some carbonate. The proportion of organic matter is small and no uric acid can be detected. Under the microscope it is seen to consist of irregular layers."

It is a common occurrence to have nephritis follow an attack of scarlatina. The symptoms of chill and fever, pain in the loins, etc., are common to fevers; but the history of the œdema and the condition of the urine lead me to suspect acute nephritis instead of intermittent and remittent fever in the two attacks mentioned.

The history of the attack during 1882, however, is clearly that of pyelitis. There was general pain in the back and abdomen, while suppuration was announced by rigors and high temperature.

The most notable feature of this case is, that nature, in endeavoring to cast off the offending body, succeeded in entirely expelling it from the kidney, and seemingly repaired the damage done to that organ.

It is one year since the operation, and the patient is in good health. The fistula remains, and she insists that there is an occasional escape of gas; indeed, she states that after an injection of glycerin and iodoform into the fistula, "the yellow powder" was seen in a discharge from the bowels soon after. Is it possible that during the suppurative stage of her disease some calculi found their way into the colon and thus formed a direct communication between the fistula and that organ?

In searching through medical literature the first mention of cases resembling the one just reported is made in the *Lafitte Mémoires de l'Académie Royale de Chirurgie*, 1753, vol. ii. p. 233. Three cases coming under the author's observation are reported:

Case I. occurred in 1734. A fistulous track, resulting from a lumbar abscess, was enlarged by Lafitte and two stones were extracted. The patient was cured.

Case II.—Abscess occurred in 1727, and a stone was extracted in 1738. Recovery.

Case III.—An abscess formed in 1741, and the stone was spontaneously expelled through the fistulous opening six years later.

In conclusion, Lafitte adds a case reported by Gaspard Bauhin, of a girl who had a tumor in the lumbar region following total suppression of urine. After poulticing for two months the surgeon distinguished a hard point in the tumor. This he incised, and from it extracted two stones. The patient was cured.

The foregoing cases may have more interest from a historical than from a practical point of view, since the records are somewhat vague; but they certainly show the recognition of such a condition at that time.

In 1797 Hermann Schützercrants[1] published the case of a patient aged fifty-six years, in whom a stone formed in the right kidney and was extracted through an abscess in the back. During the year 1777 she complained for months of continued pain in her back and loins. This was followed by high temperature, vomiting, and the formation of a soft, œdematous swelling in the right hypochondrium. In the course of twelve or more days distinct fluctuation necessitated an incision, which was followed by a free discharge of pus. Pain and fever abated, and at the end of a fortnight the discharge became thin and watery, with a distinctly urinous odor. A probe introduced into the abscess came in contact with a hard, roughened substance. The opening was enlarged and the stone extracted by forceps. The discharge of urine gradually diminished and at the end of a fortnight entirely ceased.

Thomas Annandale[1] reports the case of a patient aged forty-two years in whom, in 1868, a lumbar abscess formed, was lanced, and discharged healthy pus. Three months later a small, triangular-shaped calculus escaped, and still later some gritty particles were removed from the margin. No urine passed through the fistula. It became necessary to re-open the wound at a later period, when portions of soft calculous matter were extracted. The wound remaining open after several months, Mr. Annandale was consulted, and, on passing a probe for three inches, encountered a hard body. Enlarging the sinus, he extracted a stone weighing 72 grains. Rapid recovery resulted.

This is the latest case recorded which, strictly speaking, belongs to a class of lumbar abscesses resulting from calculi expelled from the kidney through the back, in which the kidney apparently suffered little or no destructive injury. This may be explained by the fact that the correct diagnosis and the treatment of lumbar abscess by an exploratory incision, and, if called for, by nephrotomy or nephrectomy, render cases of neglected abscess exceedingly rare.

1010 Clinton Street.

THE INDICATIONS FOR SOME OF THE APPLICATIONS COMMONLY USED IN THE TREATMENT OF CHRONIC GRANULAR LIDS.[2]

By G. E. de SCHWEINITZ, M.D.,

OPHTHALMIC SURGEON TO THE PHILADELPHIA AND CHILDREN'S HOSPITALS; OPHTHALMOLOGIST TO THE ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

The success of the medical treatment of a case of chronic granular conjunctivitis depends upon the application of some remedial agent to produce absorption of the "granulations" which are the essential characteristic of the disorder; and, moreover, to bring about this absorption without destruction of the mucous membrane and the production of changes more unfortunate than the original disease.

In the sections on the treatment of trachoma in text-books occasionally one meets with a sentence reading, "for routine treatment nothing is so effectual" as such and such a caustic application. Precisely on account of this "routine treatment" many patients wander from clinic to clinic only partially relieved. The extreme slowness with which the granulations absorb, and the tedious nature of well-established granular disease of the conjunctiva

[1] Edinburgh Medical Journal, 1869, xv. pp. 21–29.

[2] Portion of the paper on the "Medical and Surgical Treatment of the Granular Lids," read to the D. Hayes Agnew Surgical Society of the undergraduates of the Medical Department of the University of Pennsylvania, December 19, 1890.

are the reasons why ophthalmologists have sought to relegate the treatment of this affection to surgical procedures, and there is no doubt that numbers of cases are managed more successfully by methods distinctly surgical than by astringent and caustic applications. However this cannot always be accomplished, nor is it always wise, and the best method of using the so-called ordinary remedies must be learned.

For the present we will omit reference to operative interference and to the treatment of acute granulations, chronic blennorrhœa (sometimes, but improperly, classed with granular disease), and that form of granulations found in the conjunctiva which by some authors has been called *follicular conjunctivitis*, and classified as a disease separate from true trachoma, and by others looked upon as a mild form of trachoma from which the most severe types may develop. As is well known, the nature of the granulations found in this disease has not been definitely settled, and great difference of opinion as to their origin exist, although the latest researches seem to show that they arise from the natural lymphatic follicles of the part, and that it is the follicles through their changes which originate all the anatomical and clinical qualities of trachoma.

Professor Raehlmann, of Dorpat, who holds views in regard to the origin and nature of trachoma somewhat at variance with those of many other authors, has recently given a description of the life-history of the "granulations" which furnishes a convenient basis for my remarks on their treatment. According to this author, the severe forms of trachoma may arise from the mild varieties which have just been referred to as follicular conjunctivitis, or may develop independently, and are characterized by a follicular eruption, in masses, situated not alone on the surface of the conjunctiva, but also in the depth of the tissue which is infiltrated, and whose circulation is checked, causing partial or extensive disturbance of its surroundings. At first the mucous membrane, of a pale-red or yellowish-gray color, is unevenly rough, slightly or not at all folded, and contains the follicles. These increasing form closely-packed masses side by side and above one another, in such a manner as to compress the true conjunctival tissue and choke its circulation. The mucosa becomes greater and greater in volume, the contents of the follicles soften and ulcers are formed. The infiltration of the neighboring tissue assists in the egress of the contents of the follicles, and brings about a prolapse of the bottom of the ulcer and the formation of warty protuberances. During this ulcerative stage there may be photophobia, lachrymation, and profuse secretion, together with fresh pannus or exacerbations of previously-existing pannus. This pannus consists in the development of closely-packed vessels in the superficial layers of the cornea, sometimes attended by the development of ulcers and formerly believed to be dependent upon a mechanical process; that is, upon the scraping of the roughened lids across the cornea, but described by the author we are now quoting not as a traumatic irritation, but as an independent corneal complication, or follicular formation with lymphoid infiltration, analogous to the conjunctival disease. As the process continues while the surface of the conjunctiva remains rough, distinct prominences are wanting, and the final stage begins to appear, namely, cicatrization. The cicatricial tissue forms from the old follicles, new ones in the meantime arising, act upon the tarsus previously softened by a lymphoid infiltration, and produce the common deformities of the lid and its margin, namely, entropion, distichiasis, and trichiasis.

In addition to the facts thus quoted in regard to the pathological anatomy of this disease it is important to remember that it is directly contagious, especially during the stage of ulceration and free secretion; that it increases the susceptibility of the conjunctiva to take on acute inflammatory reaction; that it may become an endemic disease in crowded institutions; that certain races, especially the Irish, Jews, and Eastern races, are peculiarly liable, while the negro is almost exempt; that it is more common in low-lying regions, and it is said not to occur at an altitude above 1000 feet; and, finally, that there is much evidence to show its dependence upon a specific microörganism, which, however, has not been positively isolated.[1]

Of the numerous applications used in the treatment of this disease the following have met with deserved favor: Strong solutions of bichloride of mercury, sulphate of copper, either in the form of a crystal, or as *lapis divinus*, which consists of alum, nitrate of potassium, and sulphate of copper fused together, and camphor equal to one-fiftieth of the whole added, and the preparation run into a mould to form a stick; nitrate of silver in solutions of varying strength according to the exigencies of each case, or as the mitigated stick, and boroglyceride.

Taking a case in which there is conspicuous lymphoid infiltration of the conjunctiva, but without mucopurulent discharge, and unassociated with much hypertrophy of the papillary layer of the conjunctiva, the lid should be everted, and all portions of the mucous membrane upon which the follicular eruption can be detected carefully touched with a small mop of absorbent cotton previously dipped in

[1] Burnett (THE MEDICAL NEWS, November 22, 1890), quoting Prof. G. C. Kober, states that trachoma has been seen at an altitude of 4700 feet, particularly among Indians.

a solution of bichloride of mercury, 1 to 500. The conjunctiva lining the lids passes to the ball through a somewhat loose reflection of the membrane forming in the upper and lower lids the fornix, or retrotarsal fold. Now sometimes, when the upper lids are everted, this will come into view, but sometimes it will not, and many mistakes are made simply by turning the lids without an endeavor to bring this fold, which is particularly liable to infiltration with the granulations, into prominence. This usually can be accomplished by making the patient roll the eye strongly downward. If this is not sufficient it is better to evert the lid over a spatula and push the fold into view. This little detail deserves attention, as failure to accomplish it successfully means failure to apply the local remedy on the spot where it is most needed. I have many times watched attendants in hospitals making applications which never reached more than the anterior portion of the everted lids, totally failing to come into contact with the transmission fold tucked back and under the crease of the turned lid. If instead of the conspicuous lymphoid infiltration just stated the granulations are more dense, more elevated, and rougher, the strength of the bichloride solution may be increased 1 to 300. At first every other day, and afterward three times a week, is sufficient for this application, and at the same time the eyes should be thoroughly irrigated four times a day or oftener with a tepid solution of the same drug of a strength of 1 to 7000. It requires some judgment to know how often to repeat the stronger application, a safe rule for this and for all instances being the amount of reaction produced, and it is wise never to repeat a severe topical medication while the irritation of a previous application is still pronounced. This treatment, which a few years ago was especially advocated by Staderini, Arnauts, and others, in a great many instances is the most satisfactory of the local applications. It may be used whether pannus is present or not, and I do not believe it is contra-indicated even when ulceration of the cornea complicates the pannus. It is easily seen that the physiological action of the application is twofold. First a powerful germicide is employed in a disease that is believed by many to be of bacterial origin; in the second place a caustic is used, but not of such a character that it destroys tissue to the detriment of the surroundings.

If, during the course of the treatment on inspection of the lids with a *loup*, a precaution it would be wise to exercise before each application, the condition which I described before, quoting from Professor Raehlmann, of ulceration of the softened follicles with extrusion of their contents is observed; or, if the case is in the stage of softening, with swelling of the papillary layer, increased pannus and mucopurulent or purulent discharge, nitrate of silver becomes the more suitable remedy. In most instances a sufficient strength is 10 grains to the ounce of water, applied with an absorbent-cotton mop. Occasionally, the strength may be increased to 15 grains, and under certain circumstances the mitigated stick may be employed. In all cases where strong solutions are used these must be neutralized with common salt, or the excess washed away with plain water. In making the application a distinct white film should form over all portions touched, and the treatment should never be repeated until the tissue thus destroyed and represented by the white film has been shed with the formation of new epithelium. Nitrate of silver, in the first place, is a powerful germicide, and, in the second place, is superficially strong but does not penetrate deeply, because the film of coagulation which it forms prevents its entrance into the subjacent tissues. When the stage of ulceration has been checked by this means, as may be found by ocular inspection and judged by the disappearance of the discharge, the bichloride of mercury treatment or one of the other caustics may be resumed. During the treatment by the application of the silver, made at such intervals as the amount of reaction teaches is wise, scrupulous cleanliness with antiseptic lotions, preferably, I think, bichloride of mercury, but, in the belief of some, saturated solutions of boric acid, should be continued. A remedy with which I have had some success, and which I do not see mentioned in the text-books, namely, hyposulphite of sodium put up with glycerin and water may be tried. At one time I used it quite extensively in the Philadelphia Hospital, and while I could not see any effect in the absorption of the granulations, it seemed to relieve the patients of the intolerable irritation of which they so constantly complained.

When by treatment a case has reached that condition in which the surface of the conjunctiva remains rough, but distinct prominences are wanting, and yellowish and white lines begin to intersect each other between the granular surface; or, in other words, when the early evidences of cicatrization are beginning, sulphate of copper or *lapis divinus* is the best application. It is rather painful but must be faithfully applied exactly in the same manner described with the other remedies, always douching the lids with cold water after its use. In the presence of discharge it does not appear to act as efficaciously as at other times, but in all other stages it is useful, in the belief of many, the most useful local medication. It should be remembered now that we have to deal with a caustic not severe enough to destroy healthy structures, but efficient against granular tissue, whether we believe this to be analogous to the granulation of wounds or

not. It is, moreover, a stimulant and an alterant to the mucous membrane at a time when such actions are most necessary.

During the final stage, as the granulations are gradually disappearing, and the cicatrization becoming more complete with a tendency to dryness, it seems to me that boroglyceride has a twofold action, namely, the absorption of those granulations which still remain and lessening the tendency to the production of a xerotic condition. It may be used in a strength as great as fifty per cent., but twenty per cent. usually will suffice. Many authors look with great favor upon this drug in phases of granular disease other than the one I have just described. During all of these stages of the malady, and no matter what astringent or caustic is employed, scrupulous cleanliness should be maintained by the frequent use of one of the "eye-washes" to which attention has been directed.

Much of the preservation of useful vision depends upon the successful treatment of pannus. If this is mild in character, consisting only of a few vessels in the cornea and slight roughening of the epithelium, it will disappear with the subsidence of the granulations. If it is severe in type and associated with corneal ulceration, treatment specially directed to its cure is required. The question, how much violent pannus contra-indicates the local astringent or caustic which is being applied to the granulations must be decided by observing whether the pannus is aggravated or not by the topical medication. As before stated, it has not seemed to me that bichloride of mercury acts unfavorably, but nitrate of silver and sulphate of copper require watching. During active pannus it is well to reduce the strength of the bichloride of mercury collyrium to 1 to 10,000, or substitute for it boric acid solution. Ulceration of the cornea in the presence of any change in the color of the iris, or of actual iritis, calls for atropine drops, and much relief will be afforded by hot stupes. In the absence of iritic complications eserine is the better drug, and exercises its curative action upon the solution in the continuity of the corneal tissue, and at the same time helps in dissipating the new-formed vascular structure. If the eserine, in a strength of $\frac{1}{6}$ to $\frac{1}{12}$ of a grain to the ounce, causes headache or local irritation, this may be modified by using at night a drop of atropine solution.[1] In other words, the rules for the use of eserine in this complication do not differ from those applicable to corneal ulceration uncomplicated by the presence of granular lids.

I have described old methods and commonly-used drugs, with the exception, perhaps, of the hyposulphite of sodium, the value of which is doubtful, and firmly believe that better results can be obtained with them, medically speaking, than with a host of new remedies that have not stood the test of long experience, provided the three points upon which success depends are observed, namely, complete exposure of the affected area and thorough application of the remedy; selection of the topical medication according to the stage of the disease which is present, and avoidance of unintelligent "routine treatment"; and scrupulous cleanliness by the aid of antiseptic solutions in the intervals between the use of the local caustic and astringent measures.

[1] Excellent advice in regard to the use of eserine in this connection will be found in Dr. W. F. Mittendorf's brochure on "Granular Lids and Contagious Diseases of the Eye."

AN EXPERIMENTAL AND CLINICAL STUDY OF ERGOT.[1]

By JOHN C. HEMMETER, PH.D., M.D.,
OF BALTIMORE, MD.

(Concluded from page 139)

The effect of ergot on blood-pressure. It is under this subject of inquiry that we meet with the most contradictory statements of those who have studied the question. Thus, we are informed by H. C. Wood,[2] H. Kohler,[3] and Eberty[4] that ergot causes an enormous increase in blood-pressure—when no special mention is made I refer, of course, to *arterial* pressure—basing their conclusion on kymographic observations. On the other hand, Boreischa,[5] Herrman,[6] Wernich,[7] and Handelin[8] hold that the blood-pressure is really lowered.

These discrepancies partly find an explanation in the varieties and general differences in the qualities of the ergot that was employed. We have already alluded to the manner in which pharmaceutical products of ergot vary, not only in degree, but also very decidedly in the character of their actions. Kohler[9] compared the action of the ergotin of Wiggers with that of Bonjean, and found wide differences in the character and kind of action between them. Another explanation of the differences of opinion of the authors referred to is that it can be seen from the reports of at least two of those who have stated that ergot causes a reduction in arterial pressure that doses of the drug were used which were too large to produce physiological effects—the doses were toxic and the effects also.

[1] In the first half of this paper (THE MEDICAL NEWS, January 31st, p. 136), the dose of ergotole given at 3.25 should be 0.25 c.c., not 25 c.c., while the doses given at 3.57, 4.30, and 4.38, on page 137, should be 0.5 c.c., not 5 c.c.

[9] Loc. cit.

Brown-Séquard[1] maintained that the effects of ergot are of two kinds: First, physiological; causing, also, motor spasms and rise of arterial pressure. Second, pathological or toxic, causing vasomotor paralysis and reduction of arterial pressure.

Handelin[2] admits that the fall of pressure was noted after toxic doses.

Dr. Charles L. Holmes[3] found that when ergot was injected into the jugular vein blood-pressure was first lowered and then considerably raised. He attempted to explain this by supposing that the ergot passing to the right side of the heart excites constriction of the bloodvessels of the lungs by locally acting on their muscular walls, and thus by lessening the supply to the aortic (systemic) circulation causes a fall of blood-pressure. But when it reaches the medulla the ergot stimulates the vasomotor centre, producing constriction of the vessels throughout the body, and, consequently, rise of blood-pressure. This view is supported by the fact that, if ergot is injected into the femoral artery, instead of a fall occurring at first, there is a rise incident to a constriction of the vessels in the limb, then a fall as soon as the ergot reaches the lungs, and, at last, a final rise due to systemic contraction of the vessels of centric origin. H. C. Wood[4] has successfully disproved this view in a very instructive paper (see, also, Wood's *Therapeutics*). He found that when ergotin is injected into a vein of a mammal it causes an immediate fall of arterial pressure which is shortly followed by an enormous rise. This is in agreement with Holmes's main statement. On dividing the cord, however (*i. e.*, causing vasomotor paralysis), Wood discovered that ergot no longer produces a rise of arterial pressure. He concludes that the rise of pressure produced by ergot with the spinal cord intact is centric in origin, due to vasomotor spasm. This overthrows the theory of Holmes regarding the local independent constriction of pulmonary arteries by ergot.

Wood explains the primary fall of pressure by the sudden introduction of a large quantity of ergot into the heart causing momentary paralysis, which passes off as the drug is removed by the circulation. This fall in pressure does not occur when the drug is gradually introduced into the circulation by hypodermic injection; and Wood[5] and Eberty[6] have shown that ergot is a direct cardiac poison.

Before we proceed to state our experiments on this point we may be permitted very briefly to present some older observations concerning the effect of ergot on the number of the heart-beats. It is established beyond a doubt that ergot in physiological doses diminishes the frequency of the pulse, and we quote, on the authority of Professor Stillé, that this fact has been independently noted by Parode, Gibbon, Arnal, Hardy, and Beatty, and also by Professors Bailly and See.[1]

These observations have been made on man, the amount of reduction varying from ten to thirty-five beats per minute. According to Landois,[2] the arterial pressure has been estimated in man to be greatly increased after ergotin injections, the method employed being that of v. Basch. In a neurasthenic patient at present under the writer's observation a fall in the number of pulse-beats from 92 to 48 occurred after taking 2 drachms of fluid extract of ergot for a congestive hemicrania. The pulse was 92 at 10.30 A.M.; at 11 A.M. a teaspoonful of a mixture containing one-half drachm of fluid extract of secale was taken, and repeated every two hours. At 6 P.M. the hemicrania was relieved and the pulse numbered 48 per minute. On the morning of the following day it was 80 per minute, no ergot having been taken during the night. Eberty,[3] also, found that ergot produces slowing of the heart-beats in mammals.

We have performed two experiments in the biological laboratory of the Johns Hopkins University on a frog's heart completely isolated and suspended in a normal salt solution. The ergot was supplied to the sinus venosus from a eudiometer. The pulsations were considerably affected in number and character. We employed the Ludwig and Coats method of isolating the frog's heart; a canula was in the inferior vena cava and one in the aorta; a delicate pen and a fine manometer recording on a

revolving cylinder, completed the apparatus. On the preceding page will be found tracings taken from the rotating drum, showing the changes in the number and character of the contractions of the isolated frog-heart which occurred within five minutes after the normal circulating medium (pure blood-serum) was replaced by a two-per-cent. solution of ergotole deprived of its alcohol.

Similar, but exaggerated, tracings were obtained when stronger solutions were used. The heart recovered when the ergotized serum was replaced by pure serum. When the heart of the frog is still in connection with the cord and brain the reduction in pulse-beats is more marked: now a two-per-cent. solution of ergotized serum will, in a period varying from three to five minutes, cause the cessation of the heart-pulsations—the heart stops in diastole. In one case, after the heart had ceased beating for thirty seconds (by watch and drum-tracings), it resumed its work after the pneumogastrics were divided and the cord severed by a pair of scissors. When a normal isolated frog's heart is fed by pure serum the sinus venosus, the atrium, the ventricle, and the truncus arteriosus contract in the order in which they have just been named and in rapid succession. When the heart is fed on ergotized serum this succession is slower. But when the heart is still in connection with the nerve-centres the succession is still slower, until only an occasional sluggish, wavy contraction passes over the dilated ventricle very much like a peristalsis. We are justified to draw from these changes in the isolated heart the conclusion that ergot causes a reduction in the number and force of the contractions of the isolated heart of the frog. Ergot, therefore, to a certain extent, acts locally, and is a poison to the muscular fibres of the heart. When the heart is still in connection with the brain and cord, however, the rate of the heart-rhythm and the force of contraction are changed to a greater degree than in the isolated heart. In a frog's heart with its nervous connections intact the rate of the rhythm, the force of contraction, the tonicity, and conduction are more altered than in the isolated organ under the same strength of ergotized serum. It is, therefore, probable that, although ergot acts to some extent locally and directly as a poison to the heart-muscle, its main influence is exerted upon the central nervous system. It was our intention to study the action of ergot on the mammalian heart, isolated according to Professor H. Newell Martin's method, in a manner similar to the one by which the alcohols had been experimented with.[1] But this method of investigation requires much and elaborate apparatus, necessitating greater preparations and more time than was at our disposal. We hope, however, to investigate in the future this particular action of ergot in the manner referred to. We can reach a fair conclusion regarding this action on the isolated mammalian heart by observing the effects of ergot after the cord has been destroyed from the cervical region downward, and the vagi cut.

In dogs and cats whose left or right carotid was connected with a manometer recording on the kymograph, and who received injections of ergotole or fluid extract of secale cornutum into the jugular vein (1 c.c. ergotole in 50 c.c. defibrinated blood), there occurred within from ten to twenty seconds a fall of arterial pressure, followed in from thirty to thirty-five seconds by a rise. In four dogs the fall of pressure was equal to 12.5 mm. of mercury. In the same animals the rise of arterial pressure following immediately upon the fall was equal to 32.5 mm. of mercury. Both of these estimates are averages. The rise is, of course, calculated from the line of normal pressure before the ergotole injection. These dogs were very nearly the same size and weight. In four cats the average rise in arterial pressure was equal to 28.2 mm. of mercury. The normal average arterial pressure in the carotids of the four dogs in question was equal to 15.4 mm. of mercury.

After destruction of the spinal cord from the cervical region downward and section of the vagi in dogs and cats, there is still a reduction of blood-pressure immediately following the injection of ergotole into the jugular vein; but this is not followed by a rise of pressure, although the pressure reaches the normal line after some time. This is in accordance with the results of H. C. Wood and others, who have demonstrated that the rise of arterial pressure under ergot is due to a centric effect of the drug, and that separation of the heart from the central nervous system prevents this rise of pressure.

The tracings on the opposite page show the action of ergot just described.

Tracing No. 4 is that of the pulsations of the heart of a dog with spinal cord and vagi intact. The primary reduction and subsequent rise of arterial pressure above the normal line are evident. Tracing No. 6 is that of a dog whose spinal cord has been destroyed and vagi cut, and in which the rate of respiration, shown before destroying these parts, was afterward kept up artificially. Attention is here directed to a reduction of blood-pressure under ergot, which is followed by a slow rise to the normal, but does not exceed it.

We have assumed with H. C. Wood that this reduction of pressure is caused by the direct action of ergot upon the heart-muscle. It is possible that

it is due to an action of the poison on the motor and trophic ganglionic nerve-cells of the heart, which have been so accurately studied by Gaskell.[1]

At present we are unable to devise a method to decide upon which of these tissues of the heart the action of ergot in primarily lowering pressure is due. In animals under curare and under the influence of chloroform or ether, the slowing of the pulse-rate is not evident and apparently does not occur. This fact we are unable to explain.

To study the slowing of the pulse-rate the isolated heart of the frog or an unnarcotized and unanæsthetized mammal should be used. In two cats in which the ergotole was slowly and gradually injected hypodermically, the blood-pressure (carotid) rose after four minutes, and there was no primary depression.

Whenever injections are made into the jugular vein, the drug should be diluted with serum or defibrinated blood, strained through sterilized linen, and warmed to the temperature of the animal. Concentrated and cold injections depress the heart's action independently of any drug contained in them.

The deductions then from this part of our investigations are—

1. Ergot reduces the number of pulse-beats per minute.

2. In the isolated frog's heart it reduces the force of the contractions.

3. It exerts a local poisonous influence on the heart of the batrachian as well as on that of the mammal when injected into the jugular vein.

4. Its main action, however, is exercised through the influence of the central nervous system.

5. It raises arterial pressure when injected into the jugular vein of mammals. The rise is preceded by a primary depression due to the local action on the heart.

6. It is impossible at present to decide whether this local action is due to an influence on the heart-muscle or on the cardiac ganglia.

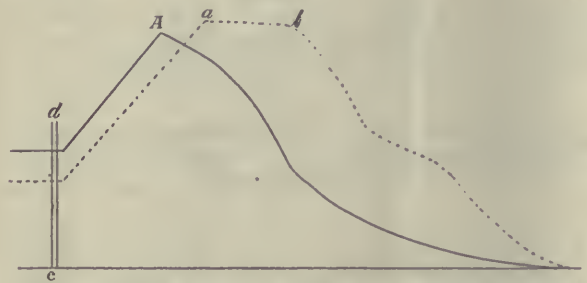
Although it is a matter of some difficulty, from the mere fact that the blood-pressure rises after the administration of a drug, to say whether the effect is due to the action of the drug on the heart or on the arterioles, yet we can come to some general conclusion regarding its mode of action by comparing the alterations which it has produced in the blood-pressure with those which occur in the pulse-rate. (Brunton.)

In the normal condition of an animal, when all the nerves are intact, a rise in the blood-pressure renders the pulse slow by increasing the normal tone of the vagus centre in the medulla, and a fall of blood-pressure quickens the pulse by diminishing the tone. In the normal animal this mechanism tends to keep the blood-pressure more or less con-

[1] Journ. Physiol., vol. iii.; also W. H. Gaskell, Muscarine and Cardiac Electric Changes, Journ. Physiol., vol. viii.; and T. Wesley Mills, Journ. Physiol., vol. vi.

stant. Lauder Brunton has supplied us with some very instructive curves and tracings bearing on this phenomenon. When alterations in pulse-rate and blood-pressure are depicted graphically, so that a rise in one curve indicates a rise in blood-pressure and a rise in the other indicates a quickening of the pulse, the two curves run in *opposite* directions if the alteration in blood-pressure is due to the arterioles, but they run parallel when the alteration is due to the heart. Thus, if the vagi be cut we find that the pulse-rate rises, and in consequence of this the blood-pressure rises also. Here the alteration in pressure is due to the heart, and the two curves are therefore parallel. In atropine-poisoning we have an analogous phenomenon.

TRACING 6.



After the injection of atropine, shown by the vertical line, the vagus is paralyzed, the pulse becomes very rapid, and the blood-pressure rises also. At *A* the vasomotor centre becomes paralyzed, the arterioles dilate, and the pressure falls. From *A* to *B* the action of the heart remains uniform notwithstanding the fall in blood-pressure, but at *B* the heart begins to become paralyzed, the pulse-rate and blood-pressure continue to fall steadily till death.

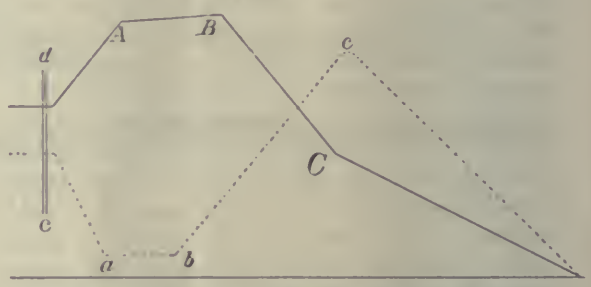
If the vagi be irritated the pulse-rate falls, and in consequence of this the blood-pressure also falls. Here again the alteration is due to the heart, and the two curves are parallel.

If, on the other hand, the arterioles are made to contract, the pressure rises, but the increased pressure stimulates the vagus roots in the medulla, and the pulse-rate falls so that the curves run in opposite directions. This phenomenon is shown in our tracings of the heart-beat and pressure under ergot. It must be borne in mind that the effect of the toxic dose of ergot is exactly the reverse of the physiological action, the latter being mainly a rise of arterial pressure, slow pulse, and general vasomotor spasm, whilst the toxic effects are fall of arterial pressure, rapid pulse, and vasomotor paralysis. These effects are graphically recorded in tracing No. 7.

From these evidences alone, therefore, we have a right to assume that the physiological rise of arterial pressure under ergot is due to its action on the arterioles, not on the heart.

Influence of ergot on body-temperature. It is especially emphasized in the reports of Wright[1] and Kersch[2] concerning the toxic effects of ergot on animals, that a low body-temperature and coldness of the surface were especially noticeable. Tessier, Gross, and Bonjean[3] confirm that this is also the case in birds, chickens, turkeys, and pigeons. A case of ergot-poisoning is reported by Dr. G. S. Oldright,[4] in which, among other symptoms, great coldness was complained of. In a case recorded by Neubert,[5] great coldness of body-surface was especially noted after ergotin-poisoning. In a case reported in the *Toledo Medical and Surgical Journal* the symptom of coldness was very prominent. We have made records of temperature observations on birds (chickens, pigeons, and sparrows) and mammals (rabbits, cats, dogs, and guinea-pigs). In sparrows the hypodermic injection of 0.2 c.c. of ergotole causes a reduction of temperature, which is lowest in forty minutes, when it begins to return to the normal. In sparrows the reduction was observed from 43° C. to 39.5° C. within thirty minutes after the injection. In pigeons a reduction from 40° to 34° in half an hour was observed after injecting 0.5 c.c. of ergotole. The temperature was taken in the cloaca. In rabbits a fall of temperature from 39° to 34.5° C. was observed one hour after injecting 0.5 c.c. of ergotole. The thermometer in case of the mammals was inserted into the rectum. In four dogs a T-shaped canula was inserted into the

TRACING 7.



In this diagram of pulse- and pressure-curves under ergot the alterations are due at first to the action of the drug on the arterioles. The unbroken line indicates blood-pressure, the dotted line indicates the pulse, the vertical double line, *c d*, indicates the time of the injection of ergot. This is followed by contractions of the arterioles and consequent rise of blood-pressure, which stimulates the vagus roots and causes slowness of the pulse. At *a* the pulse is slowest, and continues so until *b*; so far as we have physiological effect. Now at *b* the vagus becomes paralyzed (beginning toxic effect), the pulse grows quicker and the pressure rises still higher between *A* and *B*. At *B* the vasomotor centre becomes paralyzed, the arterioles dilate, pressure falls, although the pulse is rapid at *c*, the heart itself begins to be paralyzed (general toxic effect), its beats become slow and pulse and pressure fall steadily until death. (Schema borrowed from Lauder Brunton.)

carotid artery, a small thermometer was pushed into the vertical arm of the canula, and held in place by a piece of rubber tubing stripped over it, the thermometer was thus dipping into the blood current. A fall of temperature from 39.5° to 34° was recorded forty minutes after the injection of 1 c.c. of ergotole. In one dog the temperature fell to 30° C. after injecting 2.5 c.c. of ergotole. In the mammals the ergotole was injected into the jugular vein. I know of no thermometric records of human beings who had taken ergot. In the case which was reported in the preceding part of this paper in connection with the depression of the number of heart-beats under ergot, the temperature was 96° F. in the evening after taking 1½ drachms of fluid extract of ergot, the normal temperature of the patient at that time being 98° F. (mouth-temperature). I shall in the clinical portion of this work exhibit the temperature charts of patients suffering from meningitis and others with pneumonia, in which a reduction of 1.5° F. followed the hypodermic injection of ergotole (S. and D.), and rose again in one hour and fifteen minutes after the injection. After the injection was repeated it again sank 2° F. This fall of temperature occurs when the animals experimented on are not under an anæsthetic, and when curare was not used. In these cases the ergot was injected into the rectum and the sphincter ani clamped. It occurred also in animals in which the number of respirations was kept above the normal by artificial respiration. This seems to indicate that the lowering of temperature is not due to a narcotic or anæsthetic which may have been used nor to reduction of the number of respirations. The cause of the low temperature under ergot we have not been able definitely to explain. We are dealing here with a sudden, acute fall of temperature, with which the temperature of the surrounding medium has no connection.

As causes of the fall of temperature under ergot, we might suggest the following factors, viz.:

(*A*) Disturbances in the regulatory mechanisms which control the loss of heat from the body. Under this head one meets with three chief changes that might have a causative influence, viz.:

1. Dilatation of the cutaneous bloodvessels.

2. Reduction of the number of respiratory movements.

3. Reduction of the number of heart-beats and consequent loss of tone in the general circulation.

(*B*) Disturbances in the general metabolic processes.

(*C*) Impairment of the nutritive and oxygenating functions of the blood.

(*D*) Irritation of the cortical heat-centre of Landois and Eulenburg (thermic centre).

Returning to the mechanisms for reducing body-heat, which are mentioned under the first heading, we may consider first, "Dilatation of the cutaneous bloodvessels." It has been assumed, on good grounds, that there is a vasodilator centre in the medulla. This centre must undoubtedly have a potent control over heat-regulation, and would cause increased expenditure of heat by dilating the cutaneous vessels all over the body. As a matter of fact, however, ergot causes a constriction of the cutaneous bloodvessels, and from evidences given in the preceding part of this paper this explanation of the fall of temperature is invalid.

(2) That the low temperature is not caused by a reduction in the number of respirations we know from the fact that the loss of heat occurs in animals in which artificial respirations are kept above the normal number. The temperature of such animals was taken by pushing a thermometer into a T-shaped canula in the carotid.

(3) The third factor under heading 1 comprises reduction of number of systolic contractions and the circulatory changes depending thereon, as causes of the reduction of body-temperature. We know that every cardiac contraction in itself causes heat; it sets the blood in movement and this motion is, for the most part, turned into heat within the body by friction within the bloodvessels. We know that under ergot the cardiac contractions are reduced in number, force, and tonicity, and, therefore, we are justified in concluding that this is at least one causative factor in reducing the temperature. The question might arise whether the reduced action of the heart is a cause or a result of the fall of temperature. As the number of heart-beats are, as a rule, reduced long before the temperature (in most cases of hypodermic injection of ergot within two minutes, the temperature remaining normal for from ten to fifteen minutes more) we may conclude that the slowing of the heart, inasmuch as it precedes the fall of temperature, is a cause, not a result of the loss of heat.

(*B*) Disturbances in metabolism lower the body-temperature. It is more than probable that a drug that affects the general force of the circulation, as ergot does, must necessarily impair the general metabolism. This is also a constant observation in the (trophic) nutritive disturbances of ergotism. The quantity of urea in the urine of animals taking ergot might serve as a key to the degree of metabolism of the body. We hope to be able to publish in the near future a number of experiments on this subject, in which a quantitative reduction of urea in the urine of dogs is demonstrated, the animals having for two days been kept on the same quantity of meat food as in the two days preceding the analysis. We employed the sodium hypobromite method (Knop, Hufner), improved by Dr. J. R. Duggan,[1]

[1] American Chemical Journal.

for quantitative estimation of urea. Ergot, therefore, seems to act like quinine in reducing temperature, and, at the same time, the amount of urea in the urine. There is, however, some doubt as to whether the reduction of the quantity of urea is really an infallible proof of reduced metabolism. We shall consider the reduction in the total amount of liquid urine, which is said by some authors to occur under ergot, in the clinical part of this report to be subsequently published. On the whole, therefore, and judging from its effects on the heart and on the circulation, and from the phenomena of ergotism, we are disposed to believe that ergot diminishes general metabolism, and that this may be a cause of the fall of temperature under its influence.

(*C*) Impairment of the nutritive and oxygenating functions of the histological elements of the blood may by reducing the oxidation processes lower body-temperature. Our efforts to detect any changes in the structure of the red and colorless corpuscles in ergotized animals have been negative. Nevertheless, it is possible that such histological changes do occur in the blood elements. They have been shown to occur under alcohol by Herrman,[1] by Jaillet and Hayem,[2] and by C. H. Schulz.[3] By closer and careful spectroscopic, microscopic, and micro-chemical study such changes may later on be shown to occur as an effect of ergot.

(*D*) Landois and Eulenburg have discovered a cortical heat (thermic) centre in the gray matter of the cerebrum of the dog, near the centres for the flexors and rotators of the anterior extremity, situated near the lateral end of the sulcus cruciatus Local electric stimulation of this centre causes a reduction in the temperature in the extremities of the opposite side of the body. Extirpation of this region causes great rise of temperature in the extremities of the opposite side of the body (confirmed by Hitzig, Bechterew, Wood, and others). It is probable that ergot acts by stimulating this centre. This is a matter which cannot be experimentally established, as section or destruction of the cord, which would be necessary to confine this effect on the brain cortex, causes vasomotor paralysis, dilatation of the vessels, and fall of temperature in itself (Landois).

Under the head of reduced action of the heart under ergot we should have referred to the experiments of Landois and Ammon, who caused an enormous slowing of the heart-beat in rabbits by stimulating the peripheral end of the vagus for one and a half hours. The velocity of the blood-current was also much reduced. At the same time the temperature in the rectum sank from 39° to 34.5° C. Landois thinks that this weakened circulation and reduced heart-action are analogous to a reduction of oxidation processes, so that the causes which we have stated under headings (*B*) and (*C*) are etiologically very closely connected.

When discussing uterine peristalsis we omitted to mention that we made efforts to get graphic records of the uterine contractions by means of a manometer; this method has been successfully used by Schatz in Germany. Thus far our results in this particular have been negative. The cervical canal of rabbits and dogs being too small to allow the introduction of the smallest manometer we could make, this method will be tried with larger animals, and perhaps included in the clinical part of this paper. It would appear to be especially applicable for obtaining graphic records from larger mammalia, perhaps even from the human uterus.

ON THE RELATION OF ECZEMA TO DISTURBANCES OF THE NERVOUS SYSTEM.[1]

BY L. DUNCAN BULKLEY, A.M., M.D.,
ATTENDING PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL.

(Concluded from page 133.)

2. NERVOUS AND MENTAL SHOCK.

THE effect of nervous shock and violent emotions, such as grief, anger, etc., in the production of eczema has long been recognized by writers on dermatology, and the well-authenticated instances of this on record are so numerous that it cannot be questioned that this form of nervous disturbance often operates either to produce the disease or to excite an attack in one susceptible to the same. The limits of this article do not permit even a reference to the many statements supporting this proposition by observers of the highest standing, or to the many cases which have been reported. Meyer[2] has collected a large amount of material bearing on this subject, and gives a number of illustrative cases. Leloir[3] has also studied the matter very closely, and relates several very striking cases: a single one of these will serve to illustrate this portion of our subject.

A young woman who had never had any eruption previously except a pustular disease of the scalp at two years of age, but who was very nervous and impressionable, and who was in perfect health, suffered a violent mental shock, as follows: Approaching her home she saw her little child leaning out of the window, and on the point of falling; she cried out, and the child being startled, let go her hold and fell, strangely enough, directly into her arms,

[1] Prepared by special request, to open a discussion on eczema at the Tenth International Medical Congress, Berlin, 1890.
[2] Meyer: De l'Influence des Emotions morales, etc., Paris, 1876.
[3] Leloir: Des Dermatoses par Choc moral. Ann. de Derm., et de Syph., 1887, p. 373.

so that it received no harm. But the mother lost consciousness, and was completely broken down by the shock, and within three days developed a sharp attack of eczema, beginning on the upper extremities and invading much of the surface. Some months afterward she had a second and a third attack, each time following mental disturbance.

The same writer records several similar cases. Tommasoli[1] reports the occurrence of eczema after long grief and sudden shock.

Mental and moral shock occurring in many different manners have been observed to be followed quickly by attacks of eczema; thus Radouan[2] reports that cases occurred in immediate consequence of the siege and Commune of Paris, in 1871, and I myself saw more than one case ascribable to the financial panic in Wall Street, known as "Black Friday," several years ago.

3. Reflex Phenomena: (*a*) of Internal Origin; (*b*) Peripheral.

That reflex irritation is capable of exciting disease in other organs than the skin has long been an established fact, and reflex neuroses are among the most interesting phenomena seen in medical and surgical practice. This causation of eczema has also long been recognized, and clinical illustration in abundance could be cited, were it necessary or did time and space permit.

This reflex stimulation may come from within, or it may result from external irritation of the skin; in either case the eruption excited may cease with the removal of the cause, or may persist indefinitely.

a. Reflex Eczema of Internal Origin.

The simplest, and perhaps the most frequent, instance of the reflex excitation of eczema from an internal cause is that observed in teething infants, in which each accession of a tooth will cause a fresh outbreak of eruption on the cheeks, forehead, chin, or elsewhere. Intestinal irritation by indigestible food may likewise induce attacks of eczema in the same manner as in some subjects it gives rise to urticaria, and Scarenzio[3] narrates two cases in which the eruption of eczema was due to the presence of tapeworm and one in which it depended on the oxyuris.

Danlos[4] has made a very careful study of the relation between the menstrual function and diseases of the skin, and reports a number of cases of eczema in which there was a most remarkable connection between the appearance of the eruption and the occurrence of the menstrual flow; in some instances the accessions of eczema were observed a considerable number of times, and I myself have frequently remarked the same in a number of patients. Danlos also quotes Raciborsky as mentioning having observed this connection, and Tilt[1] speaks of the same. Hebra[2] states that he has seen women in whom each pregnancy was accompanied by an eruption of eczema on the hands. Bangs[3] reports pruritus and eczema of the anal region dependent upon a reflex irritation from urethral stricture.

Richey[4] has recorded a most interesting case in which an erythematous and vesicular eczema appeared on the cheeks of a little girl of ten years each time that she used her eyes to any extent. She suffered from ametropia, and when this was relieved by proper lenses the eruptions ceased to appear, in spite of great use of the eyes. I have recently had under my care a most striking case in a lady aged about fifty years, in whom attempts to use the eyes had repeatedly precipitated a severe attack of eczema beginning on the eyelids; this occurred many times before I saw her, and happened a number of times under my own observation. I have seen several other striking instances more or less similar, and oculists have mentioned to me that the same was not very uncommon in their experience. Juler[5] has treated of the reflex origin of eczema in connection with eye troubles.

b. Reflex Eczema of Peripheral Origin.

Although it undoubtedly happens that external irritants may and do produce an eruption of eczema in a reflex manner, the clinical evidence of this has not been as fully reported as that with reference to other portions of our subject. The instance reported by Kroll[6] is, however, very striking:

A woman, thirty-nine years of age, received a severe scald of the right cheek, followed by cicatrization. Under treatment by collodion a severe eczema developed on the cheek, followed by vesicles on the fingers, hand, and arm of the same side. Shortly after eczema appeared on the left cheek, and then on the left hand and arm.

It was thought that the eruption developed on the extremity through a reflex irritation from the auricularis magnus, by means of the communication of the cervical with the brachial plexus. This is further confirmed by Tidenat,[7] who describes persis-

tent eczema as a not infrequent complication of old burns.

The development of patches of eczema upon distant portions of the body is readily explained in many instances by a reflex irritation from some local patch, which may have been excited by a local cause. The later symmetrical development of acute vesicular eczema on a corresponding opposite portion of the body, as one hand or foot after the other, can be satisfactorily explained by reflex action through the cord. It is well known that in scabies there is often much eruption in parts and localities where the insect has not been present; these eruptions are often explained as due solely to scratching; but, with the reflex pruritus which has led to the scratching, there is also some capillary disturbance; and relief from the itching is not obtained until the surface is torn and more or less exudate has reached the surface. In a recent paper upon pruritus the present writer[1] endeavored to show from personal observations the reflex nature of much of the itching on the surface, and if the phenomena of itching are carefully studied, on the normal or diseased skin, it will be readily seen how almost invariably a local irritation of one part will be attended with or followed by a greater or less degree of sensation in some part near by or quite distant.

4. NEUROSES: (*a*) STRUCTURAL; (*b*) FUNCTIONAL.

Closely connected with the preceding is the group of cases in which eczema has been observed to accompany, follow, or be dependent upon disease or disturbance of nerve-trunks. These may be divided into two classes, first, according as there is actual disease or damage to the nerve, and second, where no nerve lesion is known, but only functional disturbance manifested.

a. Eczema from Structural Neurosis.

The first, and perhaps clearest, evidence of this is that furnished in connection with wounds and injuries of nerve-trunks, as studied especially by Mitchell, Moorhouse, and Keen, during the late civil war in America. Mitchell[2] speaks of eczema as of frequent occurrence in those suffering from nerve injury, principally from gunshot wounds; Duménil[3] is quoted by Leloir as reporting eczema dependent upon alterations of peripheral nerves, which he describes; the same writer quotes Duplay[4] as reporting eczema secondary to traumatic neuritis in stumps after amputation. Finally, Arnozan[1] relates the case of a man sixty years old, who had never had eczema, in whom the eruption followed soon after a violent contusion of the shoulder; there were violent pains along the arm, and forty hours after the accident eczema developed along the track of the radial nerve.

b. Eczema from Functional Neurosis.

Neuralgia, like neurasthenia, is a rather indefinite term, representing an affection or condition which may be said to have little or no established pathology, but a very large clinical history; and any very definite connection, causative or otherwise, with eczema, would be difficult to demonstrate with any great certainty. But everyone who carefully studies large numbers of cases of eczema in private practice will readily find many instances among a certain class of cases with eczema, where it would seem probable that the eruption and the neurotic condition called neuralgia were in some way connected. Cavafy[2] relates a case in which a severe trigeminal neuralgia of the left side suddenly ceased, and nine days later that side of the face became red and swollen, and developed a vesicular eczema. Leloir[3] quotes Eulenburg to the same effect, and narrates two cases, communicated by Lailler, in one of which the eczema alternated with the migraine. I, myself, have seen many patients with eczema in whom neuralgia was undoubtedly a factor of some importance in the case, although the etiological relations between the two are difficult to determine. The following striking case was observed during some months:

Mrs. B., a widow, aged thirty years, was thrown on her own resources for the support of herself and mother. She took to literary pursuits, and became editor of a magazine requiring a large amount of personal work, she using the pen almost constantly. After some months she began to suffer from neuralgia of the right arm, and at the same time a papular eczema developed on the back of the arm and the radial side of the forearm, attended with most intense itching. When she ceased for a time from her great use of the hand the neuralgic pain lessened and the eruption diminished, but a return to her severe application would cause a return of both. This continued for some time, and treatment for either condition seemed to have very little effect while the arduous labors were persisted in, but yielded quite readily when work was relaxed or suspended.

Other more or less similar cases could also be related.

5. Encephalopathy and Myelopathy.

Eczema induced by disease of the brain and spinal cord must be very rare, if, indeed, it really ever occurs, as relatively few allusions to the subject can be found in literature. Meyer[1] quotes Fèvre to the effect that eczema is frequent among the insane, and the latter considers the skin alteration a trophic disorder, dependent upon modifications in the cerebro-spinal axis. He has observed that when the mental condition is obstinate the eruption also is rebellious, but that when the latter is readily cured there is reason for a more favorable prognosis for the mental derangement. Nicol[2] has also noted eczema as common among the insane. No record has been found of eczema connected with inflammatory or neoplastic disease of the brain.

A number of observers have reported eczema in connection with diseases of the spinal cord, but the evidence of this relationship is not very strong. Charcot[3] speaks of papular or lichenoid eruptions which he has often observed along the track of painful nerves in ataxia, and which he referred to a common cause with the nerve lesion, and Rendu[4] quotes Charcot as describing vesicular lesions in connection with acute and chronic myelitis. Vulpian[5] describes a papular eruption, attended with intolerable itching, which appeared at the end of attacks of fulgurating pains in a woman with ataxia, and Purdon[6] reports three cases of ataxia, in which the patient suffered from eczema of the lower extremities during the later period of the disease. Finally, Weir Mitchell[7] and Couyba[8] record eczema after wounds of the medulla.

It will be seen, however, that the positive evidence of eczema wholly dependent upon cerebral or spinal disease, is small, both actually and relatively, when compared to other nervous connections, and that this is a field in which we require further observation.

Having now reviewed, as far as possible, the anatomical, pathological, and clinical evidence accessible relating to the connection between eczema and disturbances or disease of the nervous system, let us briefly examine as to how far it goes to prove a real nerve pathology of eczema.

Before we can rightly understand the part played by the nervous system in the production of eczema, we must first clearly recognize and define what skin condition it is that we shall call eczema, for whose etiology we are searching.

First, then, we must insist upon the entire separation of *dermatitis*, pure and simple, from *eczema*.

We all know that the skin may become inflamed in various degrees from a great variety of local causes, from the mildest effect of heat or cold or mechanical action, or from various chemical and vegetable irritants, up to the most severe and destructive inflammation of its entire structure. To these different forms and degrees of skin inflammation from purely local causes, various names have been given, partly to describe the condition present and partly to express the cause. In this group belong the animal and vegetable parasitic diseases, which are to be entirely separated from the disease process long called eczema, and recognized by its clinical appearances, as will be mentioned later. All these conditions, depending wholly on local agencies, tend to pass away when the irritating cause is removed or has ceased to act: for the skin, equally with other structures of the body, has a strong tendency to return to a state of health, unless prevented by internal or external causes.

A single word must be said here in regard to an eruption or condition of the skin, to which much attention has been called of late, namely, the *seborrhœic eczema* of my esteemed friend Dr. Unna. I say "a single word," for any attempt to discuss the subject fully would carry me far beyond the proper limits of this paper. I can only say that I take issue entirely with Dr. Unna in regard to the matter referred to, and I say this after much thought, and after having seen many cases to which this diagnosis had been given by those who know well what is intended by seborrhœic eczema; I have followed the matter carefully almost from the very first appearance of Dr. Unna's publications. The most typical cases, which are mainly seen on the chest and back, I still regard as seborrhœa, while many of the less marked cases are readily recognized as other ordinary forms of eczema. Whether there is a parasite in seborrhœa I will not attempt to affirm or deny, but I cannot agree to burden eczema with this cutaneous condition, the clinical appearance, course, and treatment of which, according to my experience, differ so entirely from those which belong to eczema proper.

I claim, therefore, that if this condition, called seborrhœic eczema, is a local affair, due entirely to a parasite, and cured by anti-parasitic treatment, it is, like the other conditions alluded to, a dermatitis, and not eczema in the truest sense of the term; we but confuse our subject and increase the difficulties of study and treatment, if we retain as eczema an eruption of a distinct local nature.

[8] Couyba: Des "Troubles trophiques consequetives, etc." Thèse de Paris, 1871.

Excluding, then, all doubtful conditions, and taking eczema as we all know it, we must recognize the three main forms into which it has long been divided clinically:

1. Acute, newly-developing, or recurrent eruptions in erythematous, papular, and vesicular forms, with burning, itching, etc.

2. Chronic patches of diseased skin, with thickening and itching, tending to remain long quiescent, unless irritated or removed by treatment.

3. Between these two we have the subacute form, more or less extensive, where, with chronic patches, there are also exacerbations, to a greater or less degree acute in character.

Taking, now, eczema, as here recognized, we may study it according to the three elements of causation, as mentioned in the topic proposed for discussion:

1. Can nerve-disturbance cause eczema *de novo*, or does it only produce or excite an eruption in a previously susceptible subject? and in what manner does it act?

2. How far does a diathesis predispose to or cause eczema?

3. What part, if any, is played by parasites?

In the light of the many observations which have been made on all sides, some of which have been here quoted, there can be no question whatever that an eruption of eczema may be induced, in a person who has never before experienced the same, by certain conditions or disturbances of the nervous system; in other words, we answer that nerve-influence can produce the disease *de novo;* and it is clear also that in those who are susceptible thereto the eruption may be prolonged or fresh outbreaks caused by neurotic agencies.

In regard to the manner of operation, exactly how the nerve-disturbance produces its effect upon the skin, we are not as yet in a position to speak definitely; much more light, both clinical and pathological, is required before the matter can be considered to be definitely determined.

Looking back over the clinical part of this essay we find that there is so little evidence connecting eczema with disease of the brain or spinal cord that we may practically exclude them from our consideration. Our study, therefore, narrows itself down to the terminal and conducting nerves and their ganglia, and to the sympathetic nervous system; for the influence of the nervous system certainly must be invoked to explain the phenomena briefly quoted from many observers.

Considering the branches into which we divided our subject in a reverse order, we have seen that eczema has been observed:

1. In connection with or following mechanical injuries to conducting nerves.

2. In connection with or alternating with functional disorder of conducting nerves.

3. In connection with or following peripheral reflex irritation.

4. In connection with or following internal reflex irritation.

5: In connection with or following nervous or mental shock.

6. In connection with or following upon, once or repeatedly, neurasthenia or nerve-exhaustion.

Time and space fail us to investigate or even allude to and explain the various theories which have been advanced in regard to the *modus operandi* of the nerve-influence, and these have been so well elaborated by Leloir[1] in his excellent monograph already referred to, that it would seem useless to go over the ground again. It would appear best, therefore, with him to adopt the theory proposed by Vulpian as the most plausible one, namely, that of *a diminution, more or less complete, of the trophic influence exercised by the nervous system upon the tissues.* This diminution of the trophic influence may take place, either directly (by destruction of nervous fibres or trophic centres) or in a reflex manner (by a diminution of the action of the trophic centres under the influence of centripetal excitation of these centres).

There is no question that in eczema we have also a great implication of the vasomotor system, as is constantly seen in the congestive element of the eruption; the same is also shown by the great value of ergot in certain cases, to which Lewin and Witzel[2] have called particular attention, and of which I could furnish abundant personal evidence. But, as far as has been observed, mere dilatation or contraction of the bloodvessels does not result in the more permanent changes of the skin which are found in eczema; the angio-neurotic eruptions, such as roseola, erythema, and urticaria, do not tend to pass into the chronic and infiltrated condition of the skin which is seen in eczema. While, therefore, the nerves controlling the blood-supply are also affected in eczema, the real cause of the structural changes found in the skin must be charged to the nerves presiding over nutrition and repair, and with Schwimmer[3] we must place eczema as a trophoneurosis.

What this trophic nerve-element is we cannot now say, but it is not at all necessary to believe with Samuel[4] in the existence of any special set of trophic nerves, as they have never yet been demonstrated; but clinically we know that such an action must

[1] Leloir: Recherches clin. etc., sur les Aff. cutan. d'Origine Nerveuse. Paris, 1882, p. 179.

[2] Witzel: Ueber den nervosen Character des Eczems, etc. Berlin, 1879.

[3] Schwimmer: Loc. cit., p. 121.

[4] Samuel: Die trophischen Nerven. Leipzig, 1868.

exist, even if we cannot demonstrate exactly the nerves which preside over nutrition.

The sympathetic nervous system has undoubtedly much to do with a genesis of eczema, but what share has not yet been demonstrated. The study of the influence of the sympathetic on disease is most difficult, and relatively little has been accomplished in the direction of showing actual skin lesions due to primary disease or derangement of these nerves or their ganglia. The only pathological evidence in regard to eczema is the case reported by Marcacci,[1] which has been so often quoted that it is remarkable that other observations have not been made in this line. In Marcacci's case the man, aged seventy years, having an acute, generalized eczema, died of right pneumonia. At the autopsy "the upper cervical ganglia of the sympathetic, as also of the cœliac, were visibly hyperæmic to the naked eye, and on microscopic section the changes were even much more evident." Moreover, when immersed in distilled water, acetic acid, and glycerin, the specimens showed the presence of a large number of nuclei; the nerve-cells, diminished by the lateral pressure of the nuclear mass, were turbid in their protoplasm, and marked pigmentation was found in the intercellular spaces.

This single observation is certainly far from being satisfactory proof that the sympathetic nervous system is involved in eczema, although supported by clinical evidence, and by the therapeutical proof found in the benefit obtained in many cases of obstinate eczema from galvanization of the sympathetic, or central galvanization, as already mentioned. For, still, it is by no means certain whether the hyperæmic and other changes found in the sympathetic ganglia in this case were not connected with the pneumonia quite as much as with the eczema. Further researches in this direction are urgently needed.

It would be interesting, did time permit, to study now somewhat in regard to the actual manner in which various nerve conditions operate to cause eczema, in certain cases. The question arises, How far the trophic and angio-neurotic phenomena are due to an exaggerated activity in certain nerves or ganglia, spoken of as the *lower centres*, or how far they are due to a want of control over the processes of life and health, as exercised by the *higher nervous level* or *centre?* We all know, from experience, that local or other agencies which at one time will cause the appearance of eczema in a patient, will at another time not be followed by such a result, and we very often recognize that it is because at that particular time the person is suffering from a depressed condition of health; or, in other words, that there is a lowered state of general vitality. With this there is a lowered nervous state, the patient is less under self-control, and, if a young female, may give way to hysterical manifestations. Now, in just the same manner the higher nervous centres, which undoubtedly control, to a greater or less extent, the lower centres which have to do with animal life, nutrition, assimilation, and metabolic processes, when they become weakened by prolonged strain or nervous or mental shock, they lose control of the organic processes, and errors occur which we call disease in various organs.

Thus we can explain how a local agency which in one patient, or at one time, will produce only a local dermatitis, may, in another patient or at another time, excite an inflammatory condition of the skin which will be continued in the form of eczema. Want of time and space forbids our pursuing this interesting study further, and we must here rest our case.

Having seen, now, that the nervous system plays a most important part in the *rôle* of the production of eczema, we can better understand how other elements, such as various digestive and other derangements, can act as real basic causes of the disease. But the consideration of this aspect of the question would lead us far beyond the limits proper for the present occasion, and I must leave these, with the question of diathesis and parasitic influence, to others who will follow in the discussion.

CLINICAL MEMORANDA.

SURGICAL.

A Case of Traumatic Tetanus.—The patient was a muscular negro, aged thirty-two years, who stepped upon a nail, which entered the plantar surface of the foot near the metatarso-phalangeal articulation of the little toe. The wound suppurated and was very painful, but finally healed, leaving a tender scar. Fifteen days after the injury, sharp pain was felt in the cicatrix extending to the thigh along the course of the great sciatic nerve, and finally to the spinal cord. The patient complained of severe pain in the back of his neck and head, and also of a sensation of oppression in the thorax. About twenty-four hours after the pain was first felt in the scar, the muscles of his jaws became rigid, sore, and painful, and his mouth could be opened with difficulty only. In three more days the mouth could not be opened, and all the muscles of the body and extremities became rigid. Opisthotonus was very marked.

When I first saw the patient, on the fourth day of the tetanic spasms I ordered calomel 10 grains, tartar emetic ⅓ grain, and croton oil 3 drops; followed by chloral and bromide of potassium of each 25 grains every two hours. The latter drugs were given throughout the course of the disease. On every third day I gave 3 drops of croton oil, which produced three or four watery stools in twenty-four hours. I made a crucial

incision in the scar, producing a venous hæmorrhage, then dressed the wound with oil of turpentine. When the heart showed signs of weakness I gave 25 drops of tincture of digitalis and 1 ounce of whiskey four times daily. When the temperature rose above 103° F., I gave 12 grains of quinine, not only for its antipyretic effect but for the antizymotic action. The patient's diet was exclusively liquid. On the twelfth day he could open his mouth. He had only two general convulsions after the bromide and chloral were first given, and on the twentieth day he was out of bed.

As this is the second case of traumatic tetanus I have successfully treated in this manner, the method seems worth noticing.

W. R. JACKSON, M.D.,
Visiting Physician to the City Hospital,
Mobile, Alabama.

THERAPEUTICAL.

Hints on the Treatment of Chronic Bronchial Catarrh or "Winter Cough."—I wish to call attention to the use of some old, but neglected, remedies which I have used during the past four years with great satisfaction in the treatment of chronic bronchitis.

Antimonium sulphuratum or "golden sulphuret of antimony," United States Dispensatory, p. 208, fifteenth edition, gives the best results in cases in which the expectoration has assumed a yellow or greenish-yellow color and is profuse, almost suffocative in quantity. It should be given triturated with milk sugar in doses of from $\frac{1}{30}$ to $\frac{1}{30}$ of a grain after meals and at bedtime; it may be administered with other remedies to quiet cough and allay fever, and as most cases of chronic bronchitis with profuse secretion have slight fever, I usually prescribe tincture of aconite $\frac{1}{5}$ minim, tincture of bryonia $\frac{1}{10}$ minim, and tincture of belladonna $\frac{1}{10}$ minim, and if cough is troublesome, either codeine or chlorodyne is given on sugar at bedtime.

After the expectoration becomes thick, bluish-white and tenacious—like boiled starch—and causes gagging, bichromate of potassium in doses of from $\frac{1}{30}$ to $\frac{1}{30}$ grain may take the place of the antimony salt, or may be given with it.

This method of treament will give excellent results in many cases of phthisis.

THEODORE G. DAVIS, M.D.
BRIDGETON, N. J.

MEDICAL PROGRESS.

A Fish-bone Impacted in the Rectum.—DR. HENRY LEE (*Lancet*, January 17, 1891) reports the case of a man who had been treated for about two and a half years for dysentery. On examining the rectum, Dr. Lee discovered a fish-bone about two and one-half inches long impacted across the bowel about two inches from the anus. The bone was removed through a speculum by means of a pair of long forceps. The dysenteric symptoms, from which the patient was suffering, immediately ceased.

Nephrolithotomy after Nephrectomy.—MR. CLEMENT LUCAS (*Lancet*, January 17, 1891) reports a case of nephrolithotomy in a woman from whom three months previously the right kidney, containing a mass of stones, had been removed. The nephrolithotomy was performed on the fifth day of total suppression of urine, with violent pain radiating from the left lumbar region. Cutting down on the kidney, Mr. Lucas discovered a conical stone about three-fourths of an inch long, acting as a ball-valve to the opening of the ureter. For the first twelve days after the operation the urine passed through the wound only, but after the nineteenth day it passed entirely by the natural channel. Healing was complete ten weeks after the operation. The operation was performed in 1885, and the patient has remained in excellent health.

Sodium Chloride in Anæmia.—DR. E. FRANK (*Prager medicinische Wochenschrift*) reports two cases of acute anæmia due to hæmorrhage, in which death seemed unavoidable, but which improved rapidly under subcutaneous injections of a sterilized sodium chloride solution (six-tenths of one per cent). In one case 500 grammes, in the other case 400 grammes, were injected inside of one hour.

Traumatic Ciliary Neuralgia.—EVERBASH reports an interesting case of traumatic ciliary neuralgia, caused by the point of a needle penetrating the eyeball at the sclero-corneal junction. The injury healed promptly, and left no objective sign to account for the subjective symptoms. He found the pupil slightly dilated and irregular, there being a projection opposite the wound, which disappeared under atropine. This indicated in all probability a circumscribed detachment of the iris from its ciliary insertion. The neuralgia may have resulted from primary injury of a nerve-filament or from pressure on the latter through distortion by scar-formation. By the galvano-cautery the focus of irritation was removed, after which the subjective symptoms disappeared promptly.—*Münchener medicinische Wochenschrift*, No. 51, 1890.

A Mixture for Irritability of the Bladder.—In the *Gazette de Gynécologie* the following prescription for irritability of the bladder is given:

℞.—Benzoic acid	15	grains.
Borax	1½	drachms.
Water	5	ounces.—M.

Dose, one tablespoonful three times a day. The mixture produces a decrease in the frequency of urination and lessens the irritability of the walls of the bladder, which are in an abnormal state owing to the phosphates in the urine.

The Treatment of Metrorrhagia.—The *Gazette de Gynécologie* quotes the following prescription:

℞.—Ergotin	2½	drachms.
Glycerin	5	"
Salicylic acid	30	grains.
Distilled water	2½	ounces.

A tablespoonful of this mixture is to be added to 3 tablespoonfuls of water and injected into the rectum once a day after the bowel has been emptied. At the same time it is well to give the following pill:

℞.—Hydrochlorate of hydrastinine, 1 grain.
Powdered liqorice, a sufficient quantity.
Make into 10 pills, one of which should be given each day. If the flow is profuse, two pills may be given.

Local Applications of Boric Acid to Relieve Constipation.—According to the *London Medical Recorder*, DR. PLATAN, of Berlin, suggests the insufflation into the rectum of a pinch of boric acid, to relieve constipation. The results are said to be excellent even in severe cases in which mechanical measures have failed.

Treatment of Chilblains.—BROCQ and BESNIER use the following treatment for chilblains: When the chilblains have advanced to the point of suppuration, they first wash the affected parts perfectly clean, and then use the following application:

℞.—Alum, Borax . . . . . 1 drachm.
Rose-water . . . . . 8 ounces.

The feet are bathed with this or a solution of nitrate of silver, 1 part to 150, is painted over the affected parts. Finally, if the diseased condition is slow in healing and needs stimulation, they employ camphorated spirit 2½ ounces, tincture of cantharides from ½ to 1 drachm. Where the ulceration is very severe and sufficient to produce a slough, the parts should be thoroughly washed daily with a solution of bichloride of mercury, 1 to 2000, or with solutions of chloride of sodium.

The Sedative Effects of Atropine and Duboisine.—After a large number of observations upon the effects of atropine and duboisine, DR. N. OSTERMAYER (*Internationale klinische Rundschau*, November 9, 1890) reaches the following conclusions:

1. In cases of mental disorder atropine in doses of from $\frac{1}{64}$ to $\frac{1}{32}$ grain is undoubtedly sedative, and indirectly is also hypnotic, but cannot be recommended for general use.

2. After the continued employment of the drug the good effects are no longer produced.

3. Bad effects do not follow the use of the drug except, in some cases, slight vomiting and diarrhœa.

4. Atropine is often effective in cases which are not influenced by morphine or hyoscine.

Concerning the sulphate of duboisine, Dr. Ostermayer concludes:

1. That in irritative mental disease the effects of the drug are sure and develop rapidly, and somewhat resemble those of hyoscine, the effects appearing in from ten to fifteen minutes after the drug has been given hypodermically.

2. It has distinct hypnotic effects, sleep usually following in from twenty to thirty minutes after the administration.

In conditions of great excitement the author employed doses of from $\frac{1}{32}$ to $\frac{1}{24}$ grain, and in no case were bad effects observed.

3. After the long-continued use of the drug the effects are much less marked.

The Chloral Antipyrines.—According to GERMAIN SÉE, the monochloral and bichloral antipyrine are similar in their action to chloral, differing, however, from the latter in being less depressing to the heart and circulation. The dose of each varies from 2 to 3 grammes. They should not be used in cardiac disease with failing compensation, since they augment the blood-stasis, and therefore increase the albuminuria. They may be administered, however, with impunity as hypnotics in aortic disease in the period of compensation. They have no action upon dyspnœa, either cardiac or pulmonary. In some cases they slightly increase the secretion of urine. Compared to sulphonal and the hypnotics of the chloral series (chloralimid and chloralamid), they are much inferior on account of their depressing effect upon the vessels and heart, though this depressing action is less marked than is that of chloral.—*La Médecine Moderne*, December 18, 1890.

Retained Fœtus.—In the *Dublin Journal of Medical Science* for January, 1891, is given the history of a case reported by MACAN to the Royal Academy of Medicine in Ireland. The fœtus had been retained for three months after the termination of the normal period of pregnancy. Four years previously the woman had had a similar experience, and carried a fœtus for eleven months. Dr. Macan cross-examined her carefully as to the case now submitted, but got no history indicating that labor came on at the end of the ninth month and then ceased. She said she had no pains until the morning on which she was delivered, and had been in good health. About the present retention she consulted Dr. O'Brien, of Tipperary, who was acquainted with her previous history. In her former delivery her vagina was a good deal torn and became enlarged afterward. Dr. O'Brien recognized that the child had been dead for three months and that the vagina was closed, and therefore thought that ordinary delivery would be more dangerous than that by abdominal section, and believed that Porro's operation should be resorted to in order to remove the child and to prevent the accident from occurring again. When she came to Dr. Macan there was nothing but the history of the eleven months' pregnancy. He carefully examined her under ether. She had a profuse secretion of milk in the breasts; and he could feel through the vaginal walls a hard, irregular tumor, but nothing that resembled a collapsed head—for if the child had been then dead two months there should have been considerable softening of the head—so that at first he was under the impression that she had a fibroid tumor. He went to the country, and after his return he received a message by telephone that she was in hard labor with strong pains. During the extra three months she had had good health, but in the last week she had a feeling of great lassitude. On vaginal examination he found that the vault of her vagina was funnel-shaped, and he could not feel its attachments to the uterus. He put her under ether, and inserted a catheter, which brought away some decomposing blood. He then tried to break through the thin partition of the vagina with his finger and felt the hard bone of the child's head. He dilated the vagina with Barnes's bags. The extraction of the child was a very difficult process and occupied four and a half hours. Since the operation she has done very well, although she has had a rise of temperature to 101°, and washing out the uterus was attended with a fœtid smell not of the ordinary kind. There must have been some abnormality

of the muscles of the uterus, or else she would not have had these delayed labors. The placenta was an extremely interesting structure and was flattened from the tremendous compression it had undergone. There have undoubtedly been cases in which the child was retained for an indefinite time, even though the cavity of the uterus had a normal opening, but Dr. Macan said that he had never met with a case like the present.

Antiseptic Precautions in the Management of Newborn Children. — Epstein (*Jahrbücher f. Kinderheilkunde*) writes that our knowledge of infection and infectious diseases has made it possible to diminish greatly, by means of prophylactic measures, the mortality from septic diseases in newborn infants. At this period of life the diagnosis of septicæmia is not easy; fever and chills may be absent and all subjective symptoms are wanting. Intestinal catarrh and marked debility are common accompaniments of the disease. Cases in which septicæmia is acquired before or during birth are very rare. The most common avenue of entrance for septic matter is the navel, although others are possible, the danger of infection being, of course, greatest during the first few days of life, when the stump of the cord is an open wound.

Infection by way of the mouth may occur, as in cases of diphtheria, septic croup, and aphthæ. It may also be caused by the aspiration of abnormal amniotic fluid, and by contact with the diseased genitals of the mother. Prophylaxis must begin with the most careful treatment of the umbilical cord. The stump should be cleaned and surrounded with a carbolized gauze dressing, the object being to produce mummification as soon as possible, and moist dressings should be avoided. A free access of air to the stump will hasten the process of drying and healing.

The physician and nurse must first attend to the infant and then to the mother, the hands being scrupulously clean, especially while handling the cord. For the first baths of the infant a harmless antiseptic solution, such as one containing the permanganate of potassium, should be used. Repeated washing and scouring of the mouth must be avoided, as such manipulations are frequently the cause of thrush. A dirty finger must not be placed in the mouth of an infant to remove secretions, nor should a dirty instrument be used, if the child is born asphyxiated, to aid in resuscitation. The instillation of a drop of a two-per-cent. solution of nitrate of silver into each eye of newborn infants should be carried out in both private and hospital practice as a preventive of ophthalmia. With reference to artificial food, the use of sterilized milk is deemed of the utmost importance, but it must not be considered that this is a perfect substitute for mother's milk.—*Archives of Pediatrics*, January, 1891.

Treatment of Snake-bites.—In the *British Medical Journal*, January 3, 1891, Dr. T. Lauder Brunton briefly reviews the physiology of death from snake-bites, and makes some possibly useful suggestions in regard to treatment. As is well-known, death from the bites of rattlesnakes and cobras is by respiratory paralysis. Laboratory experiments have shown that animals poisoned by the cobra virus may be resuscitated by artificial respiration and kept alive for many hours, but that they finally succumb. The same result occurred in one case in man, the patient dying in a few days from pneumonia. Mueller has recommended strychnine in large doses as an antidote to snake venom, and as it is a powerful respiratory stimulant we may very reasonably hope for benefit from its use, but one grain, as has been recommended, is dangerous. It should be given in small, frequently-repeated doses, its effects being carefully observed. But the depression of the respiration and the heart are not the only effects of the poison, and violent vomiting, hæmaturia, and bloody stools are sometimes very marked symptoms. Strychnine will not counteract these effects of the poison, and, in order to prevent their occurrence, we must endeavor to aid its elimination. In trying to determine what channels serve this purpose it seemed to Dr. Brunton that elimination takes place through the salivary glands and the mucous membrane of the stomach and intestines.

Fayrer and himself found that the cobra venom had an extraordinary irritant action on mucous membranes, and when it was introduced into the stomach of a frog it caused most violent vomiting, very unusual in that animal. This experiment suggests that the vomiting which forms such a prominent symptom in many cases may be due to the poison being excreted by the mucous membrane of the stomach in much the same way as tartar emetic or apomorphine would be. If this hypothesis is correct we can readily understand why partial recovery may occur if the case is treated with artificial respiration, and yet death ultimately occur. For if the poison were eliminated into the stomach and intestines by the mucous membrane, recovery would follow; but if the venom, instead of being removed from the stomach as quickly as it was excreted, were to remain there and undergo absorption, the symptoms would return and death would ensue. It therefore seems that one should try, if possible, to remove any poison that might be eliminated, and this might be done by washing out the stomach with alcohol in some form, for example, whiskey or brandy. The want of means has prevented Dr. Brunton from trying this method, but the hypothesis seems to explain the good results obtained by the free use of whiskey or brandy internally. It is not the action of these substances on the nerve-centres that prevents death from the venom, for men bitten while drunk have died from the bite, although it is usually stated that if a man can be made drunk after he has been bitten his life will be saved. This would seem to indicate that the whiskey or brandy acts locally in the stomach, coagulating any venom which may have been excreted and preventing re-absorption. The plan that should be tested is to keep up artificial respiration, and wash out the stomach with whiskey or brandy. It is obvious that this plan might be combined with the subcutaneous injection of strychnine, and that, while the circulation and respiration are maintained by strychnine, alcohol might be freely given, and after it had been removed by vomiting or the stomach-tube, it could be repeated. This plan is not without danger, and it should first be tried in a laboratory, for large quantities of brandy or whiskey might, by their strongly irritant action in the stomach, lead to reflex depression of the circulation and fatal shock, to say nothing of gastritis in case of recovery.

CURRENT LITERATURE.

SATURDAY, FEBRUARY 7, 1891.

PARTIAL RESECTION OF THE LIVER.

HOCHENEGG adds another case of partial resection of the liver to his former publication (*Wiener klinische Wochenschrift*, No. 12, 1890). An unusually large gumma was removed by Professor Albert, by Hochenegg's method, from the margin of the right lobe; the diagnosis of gumma being made after the operation.

After burning away with the Paquelin cautery an oval ring of liver tissue over the seat of the tumor, the latter was torn from its bed by hooks and forceps, and was found to be encapsulated. The bleeding was stopped by an iodoform-gauze tampon, the parenchyma partially closed over the latter, and the portion of the liver thus treated was fixed outside of the abdominal walls by passing a fibroma-needle through the tampon and the liver-tissue on either side. The wound below was closely stitched to the liver-tissue. Hæmorrhage occurred on the second day, but was completely checked by an additional tampon.

On removing the needle on the twelfth day the liver was found fixed to the abdominal walls, and the cavity rapidly filling with healthy granulations. Though convalescence was retarded by phlebitis, with thrombus-formation in one thigh, the patient was discharged cured on the forty-fifth day.

The author claims that this method is superior to that of Tillmann, which consists of two distinct operations, namely, fixing the liver to the abdominal parietes, and, after attachment has formed, removing the diseased part. He admits that the latter method is less dangerous, but thinks that the removal of diseased tissue is not as complete as by his own operation.—*Wiener klinische Wochenschrift*, December 25, 1890.

AUTO-TOXÆMIA.

PROFESSOR V. JAKSCH, in an introductory lecture upon the clinical significance of toxæmia, distinguishes two groups of toxæmia, namely, exogenous and endogenous. Of the latter he recognizes three main varieties, as follows:

1. The toxic agents are normal products of tissue-interchange, abnormally retained in the body (uræmia, toxæmia from acute intestinal obstruction, etc.).

2. They may be the outcome of pathological processes, which change the normal course of assimilation of food and tissue-interchange, so that instead of non-toxic, toxic matter is formed. This group he names nosotoxicoses, which he subdivides into two principal divisions:

(*a*) The carbohydrates, fats, or albuminous matter, which may be decomposed abnormally and give rise to toxic products, *e. g.*, diabetic intoxication, coma carcinomatosum.

(*b*) A contagium vivum enters the body through the skin, or the respiratory or digestive tract, and develops toxic agents in the tissue on which it feeds, as in infectious diseases.

3. The toxic substance results from pathological non-toxic products, which again produce the toxic agent only under certain conditions.

This group he calls auto-toxicoses, and includes in it poisonous substances (diamine, toxalbumin) resulting from decomposition of the urine in the bladder, under certain pathological conditions, and giving rise to the condition called ammoniæmia.—*Wiener klinische Wochenschrift*, December 25, 1890.

NEPHRECTOMY FOR HÆMOPHILIA RENALIS.

PROFESSOR SENATOR reports an interesting case of hæmophilia renalis in a girl aged nineteen years. The diagnosis was made positive by the family history and the exclusion of organic cause of the hæmaturia. A hereditary tendency existed in the family of her father, who made matters worse by marrying a relative.

The seat of the bleeding was located in the right kidney by Dr. Nitze by means of an endoscope, through which he saw the blood escaping from the right ureter.

Since all medicinal measures to check the hæmorrhage failed and death by asthenia seemed unavoidable, nephrectomy was performed. The hæmaturia promptly ceased, the wound rapidly cicatrized, and four weeks after the operation the patient was discharged cured.

The excised kidney was normal, both macroscopically and microscopically.

In addition to this report, Senator reviews the two other cases of nephrectomy for obstinate hæmaturia, which have been reported, and believes that in these cases also hæmophilia was the disease, though that diagnosis was not made. In both cases life was saved apparently by the operation.

From these cases and the fact that the tendency to bleed is often confined to certain regions or organs (mostly to the nose), Senator concludes that, besides a general constitutional disease, there exists another form in which the faulty nutrition and condition of the vessels are strictly localized. This condition may be inherited as such or may appear with the development of the body.

This view opens an important therapeutic field, namely, that of removing the focus of danger, if necessary, by surgical means.—*Berlin. klin. Wochenschrift*, January 1, 1891.

THE USE OF SODIUM CHLORIDE SOLUTIONS DURING THORACENTESIS.

AFTER experiments on animals and later by trials on men, DR. S. LEWASCHEW reached the following conclusions:

A sterilized sodium chloride solution, introduced by gravity into the thoracic cavity to take the place of the exudate during thoracentesis, prevents marked fluctuations in intrathoracic pressure and permits a nearly complete removal of the effusion. It not only does no harm to the inflamed pleura,

if the proper precautions are taken, but seems to influence favorably the inflammatory process. Moreover, the operation is perfectly painless.

In Lewaschew's cases, after the procedure the inflammation gradually subsided and the greatly diluted exudate was completely absorbed.

In non-suppurative pleurisies without exception, and in recent cases of the suppurative form, no new effusion formed, one operation being sufficient.

If the operation was performed after the subsidence of the acute symptoms, recovery rapidly proceeded; if performed during the acute inflammatory stage and while the effusion was increasing, recovery was slower.

In all cases a decided rise of temperature with increased diuresis and pulmonary capacity, and decided decrease in the pectoral dulness, shortly followed the operation. These symptoms were probably the effects of absorption of the highly-diluted effusion.—*Deutsche med. Wochenschrift*, December 25, 1890.

EXTERNAL ŒSOPHAGOTOMY FOR CANCER.

Christovitch lays down the following indications for œsophagotomy in cases of cancer of the œsophagus:

1. The tumor being situated at the upper orifice of the œsophagus.

2. If the tumor is hard, the operation should be performed to avoid the consequences of a rent or a grave hæmorrhage in attempting to dilate the constriction.

He claims the following advantages of external œsophagotomy over gastrotomy:

1. As an operation it is easier to perform and less dangerous than is gastrotomy. To avoid every complication after the operation, it is necessary to make a free incision and to place an elastic bougie in the passage in order to permit the easy flow of liquids from the mouth and pharynx and from the wound.

2. The constriction is accessible to direct exploration and to attempts at dilatation, and if the tumor is found to be benign, or if a cicatricial constriction is found, the operation will produce a cure.

3. If the patient is not greatly exhausted, and if there is no great urgency, an external œsophagotomy will aid the operator in performing gastrotomy more readily and surely.

4. In every case of non-cancerous constriction of the upper portion of the œsophagus, œsophagotomy is preferable should there be indication for operative interference.

5. External œsophagotomy permits of further procedures, even resection of the cancerous portion of the œsophagus and suturing of the cut edge of the œsophagus to the edges of the cutaneous wound. —*Bulletin Générale de Thérapeutique*, December 30, 1890.

SYMPATHETIC OPHTHALMIA.

From a study of the recent literature of sympathetic ophthalmia, together with some personal observations upon the disease, E. Meyer arrives at the following conclusions:

1. Sympathetic ophthalmia of one eye appears only after traumatism of its fellow, either with or without penetration. The infectious nature of the traumatism appears to play an important *rôle* in the process.

2. The experiments of Deutschmann and the observations on experimental sympathetic ophthalmia of Gayet are not proof that the disease in man is transmitted by way of the optic nerves, although they demonstrate the anatomical possibility of that transmission.

3. The results of the autopsy on the case published by Becker (*Archiv f. Psychiatrie*, xii. 1) furnish anatomical proof of a sympathetic ophthalmia in man without alteration of the optic nerves. The possibility of the transmission in man by the ciliary nerves, or by other avenues, must be considered.

4. Enucleation of the eye primarily injured, the visual function of which cannot be preserved, is the most certain way of preventing sympathetic ophthalmia. Nevertheless, enucleation, practised even within the twenty-four hours following the injury, will not always prevent the development of inflammation in the other eye.

5. Opto-ciliary neurotomy is indisputably useful in eyes the vision of which is lost by irido-choroiditis —inflammatory, not traumatic—or by absolute glaucoma. It is inefficient in preventing sympathetic ophthalmia.

6. Resection of the optic nerve cannot as yet be regarded as sufficient to prevent sympathetic ophthalmia. In one case of resection, sympathetic ophthalmia developed fifteen days after the operation.—*Revue Générale d' Ophtalmologie*, November 30, 1890.

CORRESPONDENCE.

CHICAGO.

Drs. Gibbes and Shurly on the Etiology and Treatment of Phthisis.

By invitation of the faculty of the Post-graduate Medical School, Drs. Heneage Gibbes, of Ann Arbor, and E. L. Shurly, of Detroit, Michigan, lectured in Chicago, on the evening of January 23d, on the "Etiology and Treatment of Phthisis." The audience was large, and many of the most distinguished practitioners of the city were present. Dr. N. S. Davis presided.

Dr. Gibbes began by saying that for a number of years he had been working on the question of the unity or duality of phthisis, and that he has not yet been able to satisfy himself as to the question; for if sections of the lungs of cases in which there is consolidation are carefully examined under the microscope, we find that they may be divided into two varieties. One form is inflammatory, while the other is a new growth—tubercle. Then, as a subclass, he mentioned acute miliary tuberculosis, which he considered a separate affection, inasmuch as the symptoms are different, and the disease does not run a long course, terminating usually in two or three weeks. In this form there is no breaking-down

of the lung-tissue, or ulceration into the respiratory passages, and we never find tubercle-bacilli in the sputum. In tuberculosis we have a different state of things. By the term *tuberculosis* he meant a new growth composed of fibroid tissue in the lungs. He called it *fibroid* tissue, because it was not clear to him that it is *fibrous* tissue, the reaction not being exactly the same as that of the fibrous tissue formed by chronic inflammation. It is formed from the connective tissue of the lungs, therefore it is of a fibroid character. If we knew whether caseation in the inflammatory form of phthisis is the same as that due to the breaking-down of tubercle, it would give us a better idea of the disease than we have at present.

With regard to tubercles, it has been said that there are varieties. Now, in fifty, or even five hundred sections from a case of acute miliary tuberculosis, we will never find two tubercles identical in form. There is a sharp distinction between them. We have, on the one hand, a purely inflammatory change in which there is no attempt at any structural formation whatever; and on the other, a reticular formation. One form is inflammatory from the commencement, while the other is reticular or tubercular from the beginning, consequently we are justified in considering them as two distinct diseases. Dr. Gibbes has never been able to find tubercle in the earliest stages of involvement of the lung. In the tubercular form he has carefully examined hundreds of sections, and yet no tubercle bacilli could be found, either at the commencement or throughout the course of the disease. Furthermore, he has had cases of tuberculosis of a more chronic form, which had existed for a long time, in which (either at the commencement or during the course of the disease) absolutely no bacilli could be found in the sputum, and in which, on post-mortem examination, there were large cavities in the lungs, and sections showed the characteristic breaking-down of lung tissue.

He hoped that some one would be able in the future to show conclusively whether there is any relation between scrofula and tuberculosis.

Dr. Gibbes then dwelt upon consolidations produced in the lungs by other diseases than those he had mentioned. We have, besides the forms of tuberculosis, the lesions of syphilis, and hydatids, which are sometimes included among the consolidations of the lungs, and one other disease, namely, acute pneumonia. This condition does not clear up, but remains as a solid mass in the lungs. While it remains there it does not do much harm until some change takes place which produces an irritative action around the edge of the consolidated mass. If it is chronic, it does what a chronic inflammatory action always does, namely, it causes an increase of the fibrous tissue. After a time there is contraction, and the formation of bands of fibrous tissue caused by the inflammatory action of acute pneumonia which has not cleared up. This condition is called *fibroid phthisis.*

Dr. Gibbes closed by saying that Dr. Shurly and himself had pursued their investigations with a view to rendering inert some morbid product in the lung. They succeeded in doing this with iodoform. In their experiments they have paid little or no attention to the bacillus. They also sought for some chemical or chemicals which would combine with the morbid product in the lung, and found that the chloride of gold and sodium was efficacious. In the early part of their experimental work the remedies were given by insufflation, but later, by hypodermic injections, as they found that by this method the drugs were carried to the morbid product with greater effect.

Dr. Shurly followed, dwelling upon the subject from a clinical standpoint. He said that if the bacillus is the cause of the complex conditions known as tuberculosis, which we find in the lungs and elsewhere, we must recognize one or more theories to account for it. We have in phthisis pulmonalis three distinct clinical types. It is exceedingly difficult to distinguish acute phthisis from acute miliary tuberculosis; the course is rapid in each, and the temperature-range and symptomatology are about the same. We have another form, however, which may be properly denominated the subacute form, in which the patient has a distinct catarrhal inflammation, existing perhaps for a certain length of time in the lining membrane of the bronchial tubes with little or no constitutional disturbance, the symptoms being simply local. After a time constitutional disturbances come on, and we find that this inflammation extends to the smaller tubes, finally involving the cells. The results of this are general wasting, more pronounced constitutional disturbances, and breaking down of the tissue which involves both the bronchial tissues and that of the alveoli of the lung, followed by caseation. A peculiar suppuration takes place, and post-mortem examination will reveal cavities with indurated walls and with evidences of ordinary inflammation.

We also have a chronic form in which the constitutional disturbance is postponed for a still longer period. After a while, if the patient lives long enough, the same condition of breaking-down occurs, and we find the characteristic morbid anatomy of phthisis pulmonalis.

Dr. Shurly said it occurred to them in their experimental work that these several conditions could not possibly be identical. They found that the bacilli when inoculated in animals failed to produce general or constitutional disease; they, therefore, had to look for some other cause. They did not, and never had, denied the universality of the tubercle bacillus, but they thought it possible that it is only an agent or concomitant which brings about the condition known as phthisis. In this connection the speaker was reminded of the views advanced by Dr. N. S. Davis, in 1882, in a paper before the American Medical Association, in which he declared that "there must be some chemical or bio-chemical agent besides this bacterium (tubercle bacillus) to account for this condition of things." Many others have expressed the same doubt. It is argued by clinicians, especially in Europe, but also in America, that dried sputum, when breathed, produces the disease. The speaker could corroborate this, for by insufflation of dried sputum he had produced phthisis pulmonalis in monkeys; while if he inoculated the monkeys the disease would be general, that is, it would involve the spleen, liver, lungs, and other organs of the body. It has been stated by a number of bacteriologists and pathologists that if the sputum is dried in the sun, the virulence of the bacillus is destroyed, but in their experiments sun-dried sputum produced the disease. Does not that indi-

cate, said the speaker, that there is something accompanying the bacterium? They were thus led to think that the conditions of caseation, degeneration, and suppuration may be produced by some bio-chemical action. They have always had this idea in view, consequently their first work was done in the belief that the *fons et origo* was in the lungs, and was a germ or poison generated there, and setting up inflammatory changes. They believe that phthisis pulmonalis of the subacute form is similar in its nature to what was formerly called scrofulosis.

They began to use different substances locally to check caseation. Sulphuretted hydrogen they found is a most virulent poison. Other chemicals were also used with unsatisfactory results. They then tried chlorine gas and chloride of gold and sodium, and found that patients could inhale the gas for a considerable length of time. The idea was to stop the formation of the virus whatever it might be, probably a ptomaïne, leucomaïne, or toxalbumin. Although inhalations of the chlorine gas would not stop the process, it would check it. There were some other constitutional disturbances continually going on, which they were determined to neutralize.

Owing to the various changes which chemicals are liable to undergo in the stomach and intestines before diffusion, it was evident that the remedies should be administered hypodermically. They found at first that iodine used in this manner produced abscesses *in loco*, but further investigation disclosed the fact that these abscesses were due to chemical impurities, and after obtaining their iodine from Dr. Clark, an eminent chemist of Detroit, they experienced no further trouble from abscesses except in animals to which large doses were given. The same is true of chloride of sodium. They found, after using iodine for a considerable length of time in monkeys, that it so influenced the digestive tract that it had to be abandoned. It caused vomiting, diarrhœa, etc.

The speaker anticipates publishing some case-histories in a short time. Thus far they have treated altogether four well-marked cases of so-called general tuberculosis, two of which died, while one case is certainly very much better. The report of the fourth case he would hold in abeyance. They have also treated a number of cases of phthisis pulmonalis, including both the tubercular and pneumonic forms. Of twenty-two cases they have had six *so-called* cures—so-called because sufficient time has not elapsed to determine definitely that they are cures.

In the case of a girl who had decided laryngeal phthisis, with ulceration, cicatrization is so nearly complete that the cicatrices could be detected by the laryngoscope. She returned to her home practically well last Christmas, where a physician continued the hypodermic injections once a week.

In a case in which the upper left lung was breaking down, as evinced by moist râles, the patient was examined by two other physicians. He has been under treatment since September. He now receives a hypodermic injection every ten days, and has practically passed from treatment.

Another case, a young girl, has gone home, and, according to the latest advice, is doing well, with the exception that she has a little cough. A diagnosis of phthisis in her case was made by other physicians before she was sent to Dr. Shurly for treatment.

A fourth case is that of a school-teacher, who has resumed teaching. She coughs a little, but there is no elevation of temperature.

A fifth case, a man, brought to him with a chronic form of the disease, has left the hospital very much better. He eats well, has no elevation of temperature, and no sweats.

They have at present thirty-five cases under treatment. The case of tuberculosis, previously mentioned, is one which several outside physicians saw in Harper Hospital. Dr. Shurly thought of giving up the treatment in this case, as it is undoubtedly one of general tuberculosis. But after having had one or two relapses the patient is improving, and when he left home she was sitting up. Although she has some elevation of temperature, yet she has no sweats. She expectorates about an ounce of mucus every twenty-four hours.

The general principle of treatment, continued the speaker, seems to hinge upon the use of chlorine gas to stop caseation as far as possible, and to cut off the origin of the poison which is circulating freely through the system. In the early stages such a thing is unnecessary. It is only necessary to use iodine in these stages.

In regard to the manipulation of chlorine gas, it needs care. The air of the room should be thoroughly laden with a chloride of sodium spray before the chlorine gas is evolved.

NEWS ITEMS.

Philadelphia Polyclinic.—A course of evening lectures upon medical subjects will be given by the staff of the Philadelphia Polyclinic upon Tuesday and Friday evenings at 8 P. M., to which the members of the medical profession are cordially invited. The lectures will be as follows:

February 3, Professor John B. Roberts, "Blood-poisoning."

February 6th, Professor H. Augustus Wilson, "The First Treatment of Congenital Club-foot."

February 10th, Professor John B. Roberts, "Blood-poisoning."

February 13th, Professor Thomas J. Mays, "The Therapeutics of Pain."

February 17th, Professor Thomas J. Mays, "The Therapeutics of Pain."

February 20th, Professor S. Solis-Cohen, "The Koch Treatment of Tuberculosis."

February 24th, Professor Samuel D. Risley, "The Cause of Myopia."

February 27th, Professor S. Solis-Cohen, "The Therapeutic Relations of the Nervous System."

March 3d, Professor Samuel D. Risley, "The Treatment of Myopia,"

March 6th, Professor S. Solis-Cohen, "Neuro-medicaments."

March 10th, Professor Thomas G. Morton, "Club-foot."

March 13th, Professor John B. Deaver, "Endoscopy of the Urethra—Illustrated."

March 17th, Professor B. F. Baer, "Displacements of the Uterus."

March 20th, Professor J. Henry C. Simes, "Perverted Sexual Passion."

March 24th, Professor B. F. Baer, "Displacements of the Uterus."

March 27th, Professor B. Alexander Randall, "Aural Inflammation as a Cause of Brain Lesions."

March 31st, Professor Thomas S. K. Morton, "Asepsis and Antisepsis."

April 3d, Professor Charles K. Mills, "Brain Anatomy and Localization."

April 7th, Professor Alexander W. McCoy, "Intubation of the Larynx in Adults, and Diseases Demanding its Performance."

April 10th, Professor John B. Deaver, "Brain Surgery."

March 14th, Professor Arthur W. Watson, "Laryngeal Paralysis."

April 17th, Professor Charles K. Mills, "Methods of Studying Signs and Symptoms of Nervous Diseases."

April 21st, Professor Arthur Van Harlingen, "The Present Aspect of the Leprosy Question."

April 24th, Professor Charles K. Mills, "Mistakes in the Diagnosis of Nervous Diseases."

April 28th, Professor Edward P. Davis, "The Treatment of Delayed Labor."

May 1st, Adjunct W. M. L. Coplin, "Applied Pathology, its Value to the General Practitioner."

May 5th, Professor Edward P. Davis, "The Use of the Forceps."

May 8th, Adjunct W. M. L. Coplin, "Applied Pathology for the General Practitioner."

May 12th, Professor Edward P. Davis, "Labor in Contracted Pelves."

May 15th, Professor Louis W. Steinbach, "Suppuration."

May 19th, Professor Edward P. Davis, "Obstetrical Antisepsis."

May 22d, Professor Edward Jackson, "Eye Symptoms of Cerebral and Spinal Disease."

May 26th, Professor Edward P. Davis, "The Artificial Feeding of Infants."

May 29th, Professor Edward Jackson, "Eye Symptoms of Cerebral and Spinal Disease."

Cases, specimens, and the lantern, as well as demonstrations of endoscopy and intubation, will be used in illustration, and a most interesting series of evenings is promised, surpassing the former courses as much as the former temporary quarters are excelled by the new Polyclinic building on Lombard above Eighteenth Street.

Deprived of Medical Services.—The following article from the Pittsburg *Dispatch* is of interest to medical men in general:

"John Mesendorf, of Etna, has entered suit against Dr. G. R. B. Robinson, President of the Physicians' Protective Association, of Sharpsburg and Etna, for $10,000. damages. In the statement of his case Mr. Mesendorf alleges that he received a notice from Dr. Robinson as president of the association, stating that the physicians had organized themselves into an association to enable themselves to collect delinquent accounts. It stated that the plaintiff's account was overdue, and unless he paid it or satisfactory arrangements were made by July 1, 1890, his name would be placed on the list of delinquents, and medical attendance would be refused him. Mr. Mesendorf claims that he was not indebted to the defendant, and paid no attention to the bill or notice he had received. The defendant then, he states, without cause and maliciously, placed his name on the list of delinquents mentioned in the notice.

"For the disrepute into which his name and character have been brought, without cause, and the deprivation of medical service, Mesendorf asks $10,000 damages. Mr. Mesendorf is an old soldier and has a family. He denies that he ever contracted a bill."

The Medical and Surgical College of New Jersey.—The following preambles and resolutions relative to the Medical and Surgical College of New Jersey, were adopted by the District Medical Society for the County of Hudson on December 16, 1890:

Whereas: A certain medical institute, called the "Medical and Surgical College of the State of New Jersey," chartered by special Act of this State, approved March 17, 1870, was organized during the year 1888, and opened in three small rooms on the top floor of the general office building, No. 47 Montgomery Street, Jersey City, and

Whereas, Said alleged college has graduated several students whose diplomas have been presented to the Hudson County Board of Health, and who have been refused registration, and

Whereas, It has appeared to this Society, by good and sufficient evidence, that several members of the faculty, nearly all of whom are non-residents of this State, are either incompetent to deliver lectures on the topics assigned them, or are graduates of disreputable or fraudulent medical colleges; that the facilities for instruction in said alleged college are totally inadequate, and that no clinics, dissections or hospital practice have been or can be given; that the provisions of the charter of said college have not been observed by the authorities thereof; that the requirements of said charter, even if the same were strictly followed, are far below the standard of minimum requirements of medical colleges adopted and demanded by all medical authorities at the present time, and that, therefore, the possession of a diploma from said alleged college is no proof whatever that the holder thereof has received a good and sufficient medical education, and

Whereas, The State Board of Medical Examiners of New Jersey will introduce a bill at the next meeting of the Legislature for the purpose of repealing said charter:

Be it resolved, That the District Medical Society for the County of Hudson does hereby earnestly protest against the existence of said alleged college as an unnecessary, inadequate, and disreputable institution, tending to degrade and lower the standard of the medical profession; that the influence of this Society and of the individual members thereof be given to the support and passage of the bill to repeal said charter, and that a copy of this resolution be forwarded to the several medical societies of this State, with requests for their support and influence for the passage of said bill.

HENRY B. RUE, M.D.,
Secretary.

Rich and Poor.—There was once a rich woman who discovered that she was about to become a mother. She

did not wish to become a mother, for to do so would put her to some inconvenience, and for a short time interfere with her pleasure. So she sent for her physician, who was very noted and respectable. As a result of preventing her from becoming a mother, she died. The doctor certified that she died from peritonitis. Her remains were prepared for burial by a fashionable funeral director. Her sermon was preached by a fashionable clergyman. The fashionable doctor attended the funeral. Everybody mourned the death of the estimable Christian woman. Everybody was satisfied. "Because," said they, "whatever a rich woman, a noted doctor, a fashionable undertaker, and a swell clergyman do is all right."

There was once a poor cigarette girl, named Annie Goodwin, who discovered that she was about to become a mother. She did not wish to become a mother, for to do so would prevent her from ever making a living, except by a life of shame. So she sent for a doctor named McGonigal. As a result of preventing her from becoming a mother she died. The doctor certified that she died from peritonitis. Her remains were prepared for burial by an undertaker named Merritt. She had no funeral sermon, but was buried secretly. The police heard of it and arrested the doctor, the undertaker, the woman in whose house the cigarette girl died, a little boy, a girl friend of the dead woman, and the girl's lover. And everybody said it was horrible that so many persons should have conspired to murder the cigarette girl. They even wanted to lynch the doctor. "Because," said they, "unless such things are done by a rich woman, a noted doctor, a fashionable funeral director, and a swell clergyman, they are frightful crimes."—*Twentieth Century.*

The Medical Examiners' Bill.—Some misunderstanding seems to have arisen among certain members of the profession as to the identity of the two bills which have been presented to the Legislature of Pennsylvania. The one which goes by the name of the "Medical Examiners' Bill" is the one which was presented by Mr. Riter, of Philadelphia, and has received the unanimous endorsement of the State Medical Society of Pennsylvania and of the various County Medical Societies. The bill, which is entitled "A State Board of Medical Education," is one which has been presented by the homœopaths and eclectics, and possesses the disadvantage which we have already referred to in a previous issue, namely, a lack of fairness in representation.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 20 TO FEBRUARY 2, 1891.

By direction of the Secretary of War, the extension of leave of absence, on account of sickness, granted STEVENS G. COWDREY, *Major and Surgeon*, in Special Orders No. 302, December 27, 1890, from this office, is still further extended two months, on surgeon's certificate of disability.—Par. 13, *S. O. 19, A. G. O., Washington, D. C.*, January 23, 1891.

By direction of the Secretary of War, WILLIAM H. GARDNER, *Major and Surgeon*, is relieved from further duty in the field, and will return to his proper station.—Par. 2, *S. O. 19, A. G. O., Washington. D. C.*, January 23, 1891.

By direction of the Secretary of War, FRANCIS J. IVES, *Captain and Assistant Surgeon*, is relieved from duty at Pine Ridge Agency, South Dakota, to take effect when his services can be spared by the commanding officer of the troops there stationed, and will then return to New York City and resume his leave of absence.—Par. 9, *S. O. 107, A. G. O., Washington, D. C.*, January 21, 1891.

By direction of the Secretary of War, EDWIN F. GARDNER, *Captain and Assistant Surgeon*, is relieved from duty at Pine Ridge Agency, South Dakota, and will proceed, without delay, to Fort Riley, Kansas. and report, for temporary duty, to the commanding officer of that post.—Par. 10, *S. O. 107, A. G. O., Washington, D. C.*, January 21, 1891.

By direction of the Secretary of War, leave of absence for six months, with permission to go beyond the sea, is granted JULIUS H. PATZKI, *Major and Surgeon.*—Par. 5, *S. O. 24, A. G. O., Washington, D. C.*, January 29, 1891.

By direction of the Secretary of War, WILLIAM STEPHENSON, *Captain and Assistant Surgeon*, will proceed, without delay, from Columbus Barracks, Ohio, to Fort Wayne, Michigan, and report in person to the commanding officer of that post for temporary duty, and upon completion thereof will return to his proper station—Par. 13, *S. O. 23, A. G. O., Washington, D. C.*, January 28, 1891

By direction of the Secretary of War, ROBERT J. GIBSON, *Captain and Assistant Surgeon*, is relieved from further temporary duty in the field, to take effect so soon as his services can be spared by the officer commanding troops with which he is serving, and will then return to New Haven, Conn., and resume his leave of absence.—Par. 6, *S. O. 22, A. G. O., Washington, D. C.*, January 27, 1891.

By direction of the Secretary of War, CHARLES M. GANDY, *Captain and Assistant Surgeon*, is relieved from temporary duty in the field, to take effect when his services can be spared by the commanding officer of the troops with which he is serving, and will then return to Ocean View, Cape May County, New Jersey, and resume his leave of absence.—Par. 1, *S. O. 21, A. G. O., Washington, D. C.*, January 26, 1891.

By direction of the Secretary of War, WILLIAM O. OWENS, JR., *Captain and Assistant Surgeon*, is relieved from temporary duty with troops in the field, to take effect as soon as his services can be spared, and will then return to Muskogee, Indian Territory, and resume his leave of absence.—Par. 3, *S. O. 20, A. G. O., Washington, D. C.*, January 24, 1891.

By direction of the Secretary of War, WALTER REED, *Captain and Assistant Surgeon*, is relieved from temporary duty at Fort Keogh, Montana, to take effect as soon as his services can be spared by the commanding officer of that post, and will then return to Baltimore, Maryland, and resume his duties in that city as Attending Surgeon and Examiner of Recruits.—Par. 3, *S. O. 20, A. G. O., Washington, D. C.*, January 24, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR TWO WEEKS ENDING JANUARY 31, 1891.

PERSONS, REMUS C., *Surgeon.*—Ordered to the U.S.S. "Concord," February 10, 1891.

CRANDALL, R. P., *Assistant Surgeon.*—Ordered to examination preliminary to promotion.

BERRYHILL, T. A., *Passed Assistant Surgeon.*—Detached from the "McArthur," and wait orders to "Marion."

JONES, W. H., *Surgeon.*—Detached from "Swatara," to proceed home and is granted six weeks' leave of absence.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

REPEATED OPERATIONS ON THE SAME NERVE FOR CHRONIC FACIAL NEURALGIA.

BY EDMUND ANDREWS, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE CHICAGO MEDICAL COLLEGE AND IN THE MERCY HOSPITAL, CHICAGO.

IN an article published elsewhere, I called attention to the fact that repeated operations on the same nerve will give, after each operation, a prolonged period of relief to patients suffering from facial neuralgia. Further experience has thrown additional light on the subject, and clearly indicates a coming advance in neural surgery.

The causes of trifacial neuralgia are generally peripheral, though a few cases originate in the brain itself. The opinion is gaining ground that in superior and inferior maxillary neuralgias the point of origin is most frequently a decayed tooth, but that various injuries and diseases of the maxillary region may also be causative. Inflammation and ulceration around a tooth, or some other irritation, set up a neuritis in the corresponding nerve-twig. Generally this subsides without causing permanent injury, but in a few cases, for reasons at present unknown, the neuritis becomes progressive and advances to the main nerve-trunks. In the lower jaw, for instance, the inflammation reaches the main inferior dental nerve, and with the well-known obstinacy of neuritis proceeds backward along the dental canal, emerges from the foramen on the inner side of the ramus, creeps up the inch and a half of nerve from that point to the skull, and follows the trunk of the nerve into the foramen ovale, where it causes disease in the great semilunar ganglion just above the foramen and inside of the skull. Many cases seem to stop here permanently, causing frightful pain, referred to all of the three trunks of the trifacial, but not entering the brain. A few, however, follow the fifth nerve into the medulla oblongata, and set up a variety of cerebral disorders. In one case under my observation, the sight of both eyes was lost, either from the disease extending to the roots of the optic nerves, or to the visual centres of the brain itself. However, as previously stated, only a few progress to this extent. In the great majority of cases the inflammation seems to cease at the semilunar ganglion, causing violent pains, referred primarily to the inflamed branch, but radiating in a less degree to the other two trunks. To the patient the pain seems peripheral, though the real cause lies deep. In bad cases the paroxysms come on with violence—sometimes every fifteen minutes—with intervals of ease.

The old surgeons, like the patients, located the disease at the place where the pain seemed to be, and to this day neuralgic teeth are often pulled out in the vain hope of removing the cause of suffering.

In cases of neuralgia of the inferior dental nerve, the elder Gross advised subcutaneous section of the trunk where it emerges from the anterior mental foramen. Experience soon showed the futility of these and similar methods, and the French surgeons advocated the idea that the points of irritation were to be found in some of the numerous bony canals and foramina through which the branches of the fifth nerve pass, and instructed their pupils to resect these nerves on the proximal side of the bony canals. This proved better, and many brilliant cures, some permanent and others temporary, were thus effected. The majority of cases, however, relapse, when if a section of nerve long enough to prevent reproduction has been removed, surgeons abandon operative treatment as hopeless, unless there is enough of the stump of the nerve left to admit of a second resection.

Just here accident favored us. In a number of instances in searching for the shortened stump of a previously-resected inferior maxillary nerve, the operation resulted successfully, though not a particle of nerve-trunk could be found in the tissue removed. This, of course, led to thought and to action.

The following case is a good example:

A lady, about seventy years of age, applied for relief from a characteristic and severe chronic neuralgia of the inferior maxillary nerve. I trephined the ramus of the jaw, and picking up the trunk of the nerve with a pair of stout forceps, slowly wound it on the beak of the instrument, and broke it off some distance upward toward the point of exit from the skull, bringing away about an inch of the nerve.

The parts healed readily, and the patient was free from pain for about a year and a half. A relapse then occurred, and she begged for another operation. Though unable at first to see that any result could be expected from an operation when the nerve was out of reach, it occurred to me that the broken end of the nerve-stump must necessarily be attached to the cicatrix of the old operation, that at least I could thoroughly stretch it, and

that this might be useful just as nerve-tension is in Nussbaum's operation. I therefore operated again, cutting along the line of the old scar to avoid hæmorrhage and shock. The hole left by the trephine was closed by cicatricial tissue. With a tenotome I carefully separated the cicatricial disk from the edges of the bone and drew it a little outward, then seizing it with strong forceps I forcibly drew upon it, and slowly twisted its internal prolongation until it came away. No nerve-tissue could be found in it, but the deeper part must have been attached to the nerve-stump, and hence the latter must have been strongly stretched. There was neither shock nor hæmorrhage. The patient was again relieved, and remained free from pain for a year or two. Again she relapsed, and was again restored to comfort by a repetition of the procedure. She was thus relieved four times during a period of six years, though no nerve-tissue was exsected except at the first operation.

Similar cases have repeatedly occurred in my experience, and I think that many other surgeons have unintentionally accomplished the same thing, while pulling on the cicatrices of old operations in the hope of removing more of the stump. The mechanism of the procedure is probably as shown in the accompanying cuts.

FIG 1.

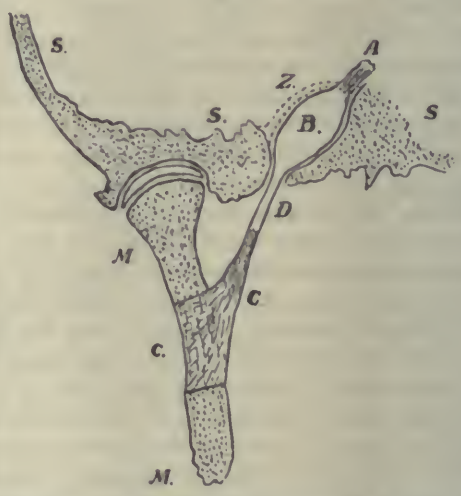
S, S, S, S. Part of base and left side of skull, cut transversely through the foramen ovale. *M, M.* Ramus of the jaw, cut nearly in the same direction. *A.* Fifth, or trifacial nerve, entering the semilunar ganglion. *B.* Semilunar ganglion, bound down by a thick roof of dura mater, indicated by the double dotted lines *Z*. *D.* Inferior dental nerve passing down through the foramen ovale to enter the foramen in the ramus at *T, K. K.* The myloid branch. *T.* The horizontally-shaded portion represents the part of the bone removed by the trephine.

Fig. 1 represents a transverse section of the left half of the base of the skull seen from behind. The line of section runs transversely through the foramen ovale and the articulation of the jaw. The ganglion *B* is viewed edgewise from behind, so that the ophthalmic and superior maxillary branches, which are in front, are not seen, but the inferior dental nerve *D* is shown, passing from the foramen ovale to the posterior dental foramen of the lower jaw, between *T* and *K*, a distance of about an inch and a half. *M M* is a section from the condyle of the jaw downward and a little forward to the bottom of the ramus. The horizontally-shaded portion *T* represents the part usually removed by the trephine.

In making a resection of the nerve, we, of course, remove the button of bone and drag the nerve out by avulsion, or divide it high up with scissors, and then draw it out. As the sheath of the nerve has countless attachments to the connective tissue, which are lacerated in dragging it out, we leave the track of a future cicatrix, extending from the end of the nerve-stump to the external wounds. In healing, the foramen made by the trephine is not closed by bone, but by a disk of cicatricial tissue adherent to the bone at its edges, and extending in a conoidal form to the divided end of the nerve.

The action of the secondary operations is doubtless as follows: The disk being separated from the bone and dragged out by force, powerful traction is made upon the attached stump of the nerve *D*.

FIG. 2.



A. Fifth nerve. *B.* Semilunar ganglion. *D.* Stump of the inferior dental nerve. *C, C.* Cicatrix filling the opening made by the trephing, and extending to the cut end of the nerve *D*. The cicatrix *C* has not the smooth, well-defined outline shown in the figure, but it constitutes a mechanical connection between the disk occupying the trephine hole and the cut end of the nerve.

In short, it produces vigorous nerve-stretching, which acts directly on the nerve-trunk itself, and effects mechanical changes in the ganglion *B*, so that in principle it is simply Nussbaum's nerve-stretching operation.

The possibility of thus repeatedly curing after relapse is of great practical value, and seems to be not generally known to authors.

Now, as nerve-stretching without resection often effects prolonged cures, it is a fair question whether resection of the nerve is necessary at all, since one might uncover the trunk, either by trephining or by the operation through the mouth, and simply stretch the nerve, and one could repeat the stretching as often as relapses occurred.

Another suggestion naturally arises. It is probable that the seat of the inflammation in chronic cases is almost always in the semilunar ganglion, and that extirpation of that organ would effect a permanent cure; but as the ganglion is situated within the cranium and lies close against the internal carotid artery, no one has yet shown us a safe method of removing it. The operation could be performed without great risk, as follows:

First raise the tissues from the outer surface of the ramus, and divide that part of the jaw below the middle, along a line commencing at the junction of the front edge of the ramus with the body of the bone and running downward and backward. Then forcibly turn the ramus outward, so as to expose the parts within it. Identify the nerve, and follow it upward and inward to its exit from the foramen ovale. A small artery enters the foramen from below, which might require torsion. Then with suitable instruments enlarge the foramen sufficiently to admit a very small curette, or other instrument capable of breaking down and removing the substance of the ganglion. The latter is roofed in above by a very strong covering of dura mater, separating it so effectually from the brain, that the convolutions need not be wounded. In the figures, the double-dotted lines *Z* indicate this covering. Along the inner border of the ganglion the internal carotid artery lies in pretty close relation, so that great care would be required in that situation. The centre of the ganglion lies nearly in the direction of a straight line drawn from the bottom of the sigmoid notch of the ramus upward and inward through the centre of the foramen ovale. After the operation, the ramus could be turned down again and wired to the body of the bone. The operation should, of course, be done antiseptically, and drainage secured at a convenient point. In those very obstinate and severe neuralgias of the fifth nerve, which render existence almost unbearable to the patient, I think this operation would offer a probability of permanent cure, and be entirely justifiable.

No. 6 SIXTEENTH STREET.

Artificial Production of Inguinal Hernia.—It is said that in Russia the Jews sometimes produce inguinal hernia in themselves in order to avoid military service. An instrument resembling a glove-stretcher is used, and by means of it the inguinal canal is gradually dilated.

AN INVESTIGATION OF THE COMPARATIVE FREQUENCY OF TYPHOID FEVER IN THE CITY OF READING AND THE COUNTY OF BERKS.

BY DANIEL B. D. BEAVER, M.D.,
SURGEON TO ST. JOSEPH'S HOSPITAL, READING, PA.

FIFTEEN years ago, while riding with a physician in an adjoining county, on his way to a patient, he pointed out a house with a remarkable history. He said that he had practised medicine in that locality for thirty years, and during that time the occupants of the house had changed every two or three years, that he had been attending physician to all the families who lived in the house during that time, and that every family had had typhoid fever while there. This remarkable story seemed to me proof that there was a local cause for the disease about the house, and impressed me with the idea that local causes for typhoid fever might generally be found, if properly sought. It also led me to question whether, if the cause of typhoid fever could cling to a farmhouse so long, reproduce itself so often, and poison so many families in succession, such a place could not become a centre of infection for people who, although living at a distance, consumed some of the food-products of the farm, in which the germs of disease might be transported.

With this question in mind, I made a number of observations during the years that have since elapsed, the results of which led to the present investigation of the comparative frequency of typhoid fever in Reading and the surrounding country. The field of this investigation embraces the city on the one hand and the rural districts of the county of Berks on the other. The year 1889 was selected because it presented a minimum amount of the disease, in both the city and county. The data upon which this report is based were obtained by mailing a series of questions to every registered physician in the city and county. The work was unfortunately delayed by the appearance of the "grippe" at the time that the questions were sent to the physicians in the county. In consequence of this, some were disabled and others so busy that replies were obtained with difficulty, and from some none at all were received because so long a time had elapsed before they could give the matter attention, that, having kept no record of cases, they could not give definite answers.

Of the 97 physicians who practised in Berks County during 1889, positive and definite answers were received from 70. These gentlemen reported 412 cases. Supposing the 27 who did not report to have had the same average number of cases, they would represent 159 cases. To these should be added 18 cases, which occurred just outside the city limits, and were attended by city physicians. The total for the county then would be 589 cases.

In the city there are 71 registered physicians, excluding specialists who do not attend fever cases. Of these, 66 reported 208 cases, and 5 did not report. Giving the latter the same average number of cases as those who reported, they would represent 16 cases. In addition to these there were treated in the two hospitals 16 cases which originated within the city limits, making a total of 240 cases for the city.

The population of Reading, as shown by the last census, was last summer 59,000, and that of the county 76,000; and for my purpose it may be assumed that the proportions were the same last year. The city, with 59,000 inhabitants had 240 cases of typhoid fever, or 1 case for every 246 residents; while the county, with 76,000 inhabitants, had 589 cases, or 1 for every 129 residents. In other words, there were in the city 4.07 cases for every 1000 inhabitants, and in the county 7.75 cases for every 1000.

Although my previous observations led me to believe that typhoid fever was more prevalent in the county than in the city, a ratio of nearly two to one is entirely beyond expectation. Indeed the difference is so striking that in the absence of corroborative statistics from other sources—and I know of none to offer—it may inspire in the reader doubts of the correctness and truthfulness of the report; and hence it may be well to state in detail the characteristics of the field embraced by the investigation, and the method by which these results were obtained.

Every physician practising in the county was addressed by letter or in person, and was requested to furnish a list of the cases of the disease he had attended during the year in his own field of work, excluding those that he saw only in consultation. Among these physicians there are a number who live just beyond the borders of Berks County and yet see many patients in the county, and others who reside in the county, but do much of their work outside of its limits. These physicians were requested to report only the cases which occurred within the county lines. The division between the city and county was made in the same way. Cases which occurred outside of the city limits, although attended by city physicians, were assigned to the county. In the records of both city and county, cases occurring in visitors or new residents, who arrived within thirty days before the appearance of the disease, were not counted.

The geological features of the county are such as would largely prevent the transmission of disease-germs through the water-courses from adjoining districts. The eastern and western borders of the county are almost on a line with the water-sheds of the Delaware and Schuylkill and the Susquehanna and Schuylkill, respectively; and the northern boundary being the summit of the Blue Ridge, the surface water of the other side reaches the Schuylkill before reaching the county.

The water-courses of the southern part of the county flow in an outward direction to empty into the Lehigh, Susquehanna, and Schuylkill Rivers. The Schuylkill, flowing in a southeasterly direction, divides the county into two almost equal sections, carrying with it the drainage of the lower Schuylkill coal-field, but its water is not used for domestic purposes either in the county or city.

The water-supply of Reading is derived from springs and brooks which arise in the mountainous districts immediately east of its boundaries. The subsoil of these districts is composed of Potsdam sandstone and Laurentian gneiss, and the water is unsurpassed for both domestic and manufacturing purposes. The section from which it comes was singularly free from typhoid fever last year, and the physicians who are familiar with the region say that the disease is very infrequent there at all times. Dr. M. L. Bertolette, of St. Lawrence, whose practice extends into the section that supplies the largest of the three storage reservoirs—an area of six and one-half square miles—states that in six years he has not seen a single case of typhoid fever there, while in the valley below there have been some cases every year.

Such testimony tends strongly to exclude our water-supply from the causes of the disease in the city, and it is corroborated by the entire absence of evidence that a single case arose from the use of the city water. On the other hand, a large number of cases, which occurred among the employées of a cotton mill, were traced directly to the use of water from a well near the mill. The exact number of these cases could not be determined without more time than I could give the matter; but it is safe to say, from information given by some of the attending physicians, that there were more than twenty-seven.

The varying geological features of the different sections of the county have an important bearing upon the distribution of this disease. The shale formations furnish a much larger proportion of cases than the limestone. This is undoubtedly owing to the greater porosity of the subsoil in the former. In the shale sections the surface is more undulating than in the limestone, and nearly all the dwellings are located in the depressions near springs. Where there are no springs, and wells are necessary, water is usually found quite near the surface. The house being near the water, the barn, privy, and other outbuildings are of necessity placed upon higher ground. Then, with a porous, sieve-like soil between the well or spring and these buildings, and the natural ten-

dency of the water which is absorbed by the higher ground to percolate to the lowest point, it becomes apparent that the germs of the disease, once thrown into a cesspool, may for a long time vitiate the water and infect successive occupants of the dwelling.

While the owners of shale lands have not recognized the evil sanitary effects of the looseness and permeability of their subsoil, they are fully aware of its blighting effect upon their crops. Some years ago an intelligent owner and occupant of a large farm in a shale region complained to me of the disadvantages under which he labored as compared with his more fortunate neighbors on the limestone lands, just a mile south of his own. He said that they, with the same labor and expense, raised much larger crops than he could. Upon being asked why he did not use fertilizers and thereby improve the soil, he replied that he had tried them, but found that while on limestone land they improved the crops for several seasons, on his the next rain carried them down into the earth far beyond the reach of the growing crops. The inference to be drawn from this farmer's statement for my purpose is, that if his spongy subsoil imbibed the fertilizers with the next rain, it would do the same with anything else that water would bring in solution to it.

In the limestone areas there are fewer springs and their flow is usually larger, and varies less in the wet and dry seasons, indicating that they are draining a larger surface, and hence that their water comes through the earth from a greater distance. Moreover the clay which overlies the rocks, being more compact, is a better filter than shale. Then again, the wells are deeper, it being a common thing to find them from thirty to fifty feet deep in limestone land.

Typhoid fever was most prevalent in the shale soil of this county, not only last year, but for a long time previously. I observed the fact and spoke of it before the Berks County Medical Society twelve or thirteen years ago. A similar observation has been made, I believe, by Pettenkoffer, of Munich, on the occurrence of the disease in the vicinity of that city.

The correctness of the primary reports upon which this observation is based is open to question, and, of course, depends upon the truthfulness and professional ability of the physicians who kindly made them.

The report from the city is as nearly correct as it can be made without the aid of every physician. To ascertain whether any of the five who did not reply to my inquiries reported deaths from typhoid fever, I examined the records of the Health Office. The name of one of the five appeared, with one case, and all the other deaths from the disease were accounted for by those who sent reports.

It is possible, then, that the five physicians from whom I had no response did not have the average number of cases with which they were credited, and that consequently the whole number in the city is a little less than has been stated.

It is a matter for regret that the investigation of the county could not be made as complete as that of the city. However, the errors which do exist are probably in favor of a larger number of cases than this report shows.

Of the twenty-seven physicians who have not responded, and who were credited with the average number of cases in making up the figures, twenty-one reside in the old slate and new red sandstone formations, in which the disease is more prevalent than in the limestone belt, and probably they had more than the average number, which would make the figures of the report too low. Moreover, I have not included in this report an outbreak of the disease which occurred in one of the school districts between Kutztown and Virginsville, in the old slate formations. This outbreak was supposed to have originated from well-water used by the school, and included a large number of cases. Most country schoolhouses are not supplied with wells, but the water is usually brought from the nearest dwelling, so that the scholars are exposed to the morbific influences which may be present in the dwellings. The school in which the outbreak occurred is situated between the residences of a number of physicians, whose practice extends throughout the district, all of whom, unfortunately, failed to report their cases. Full accounts of this endemic would have added considerably to the number of cases in the county.

In a collective investigation like this the question of the correctness of the diagnosis of the cases reported is worthy of careful consideration, but it can be answered only in the most indirect manner. Other things being equal, the diagnosis will be correct in inverse proportion to the number of families from which a given number of cases are collected, because the whole family is usually more or less exposed to the poison which caused the disease in one of its members. With this idea in mind the physicians who took part in the investigation were requested to state the number of families affected and the number of cases that occurred in each family. Unfortunately, the reports received are so imperfect that only a few can be used. Only those who had more than ten cases each have given full replies to the questions. Their figures are exhibited in the table on the next page.

It is seen that 8 country physicians return 166 cases from 83 families—an average of 2 to each family—while 7 city physicians return 100 cases from 77 families, an average of 1.3. The probabilities of correct diagnoses are then, from this point

of view, decidedly in favor of the country. These figures also indicate either that country people are more susceptible to typhoid fever than are residents of the city, or that the poison which produces the disease is more virulent, or continues its activity longer in centres of infection in the country than in the city.

Inasmuch as it has become fashionable in the large cities to blame the plumbers for the spread of typhoid fever, an effort was made to ascertain whether indoor water-closets had any bearing upon the occurrence of the disease in Reading, although the conditions are not the same, as this city has no system of house-sewerage. The bath-tubs and water-closets empty into wells, usually from ten to thirty feet from the houses, so that each building has its own sewer, and cannot through bad plumbing be affected from adjoining ones. But, the germs of the disease having once reached the cesspool of one of these houses, there is no reason why they should not find their way up the pipes and into the house as easily as if they had to start from a common sewer-pipe. The only difference, then, between a house with modern conveniences in Reading and one in a city with a common house-sewerage system, is that in the former typhoid fever must at some time have been on the premises before the house could be infected through bad plumbing, while in the latter its first appearance might be due to imperfect connection with a common sewer. The reports of the physicians upon this point were so unsatisfactory that no calculations could be based upon them, and information was then sought in the contagious-disease record of the Health Office. There the surprising fact was discovered that only 66 of the 240 cases of the disease which occurred in the city were recorded. Of these, only nine occurred in houses that pay water tax for indoor closets, and, of the nine, six were in one family, in a new house, in which typhoid fever had not previously existed, and the disease was undoubtedly due to the use of milk from an infected dairy. In the three other cases no cause outside of the dwelling has been discovered, and it is therefore possible that they may have been due to bad house-drainage. It is known that one case did arise in connection with a leaky sewage-pipe in a hotel.

Admitting that the three cases were due to this cause, we have 3 out of 66 cases, or 1 in 22. The whole number of houses in the city is 15,000, and of these 1471 have indoor water-closets—about 1 in 10. The houses with water-closets, then, show less than half as many cases of the disease as those without them.

The sources of food-supply were not examined for causative relations to the disease, except in a few cases to which the attending physicians invited attention, because the time for such an undertaking could not be spared. Inquiry in these few instances led to the discovery that eleven cases, in various parts of the city, could be traced to the use of milk from a dairy farm on which the disease had occurred during the year. There were a few other cases in which it was suspected that the milkman brought the disease, but for the reasons stated they were not scrutinized. There is, however, ground for believing that in many more instances the cause could have been traced to the source of food-supply.

After deducting the 11 cases which were due to the use of contaminated milk, and the 27 due to the use of the well-water at the cotton-mill, there remain of the 240 cases which occurred in the city 202 of which the cause is unaccounted for—an average of 3.43 per 1000 inhabitants. It is possible, but not probable, that these 202 cases arose from causes which were confined to the city. Nearly all of them occurred in houses without indoor water-closets, which, so far as infection from sewage is concerned, are in the same condition as rural homes, the cesspools being some distance away. Actually, they are under better sanitary conditions, because, in the city, cesspools must be twenty feet deep, while in the country they are frequently only a few feet in depth, and in many instances are open below and permit the ingress of fowls. Moreover, in

this city it is not possible for the cesspools to communicate with the water-supply as in the country. Does it not seem likely, then, in the absence of evidence to the contrary, that the *materies morbi* in these cases was brought here from the country in the food?

There are a few old wells still open in various parts of the city, and a small number of people use water from them during the summer. It is possible that some cases of the disease arose from the use of this water, but the matter was not examined sufficiently to warrant an opinion.

These investigations were made with as much care and labor to find the truth as it is possible to bestow by one who is otherwise engaged, and the writer believes that they will compare favorably with the best work of this kind, and that in accuracy of detail they are far superior to statistics furnished by the health offices. A large part of the spare time of the writer and an assistant was given to the work since the beginning of 1890.

What are the inferences to be drawn from it?

First, that the conditions are more favorable in the country than in the city for the propagation and dissemination of the microbe which causes typhoid fever, and that in Berks County typhoid fever is distinctly a rural disease. This inference is supported by the facts that the disease is more than twice as frequent in the country as in the city; that no food-material is taken from the city into the country which is not equally distributed in the city, and which would not produce like effects in both places; that varieties of food are brought from the country to the city which are not obtained from other sources, and that the disease has followed the distribution of some of them in the city, especially the milk; that the consensus of opinion in the profession is, that the germs of the disease are in nearly all cases imbibed with food and drink; that the conditions necessary for contamination of the food and drink in the city exist in the lowest possible degree; and that water, which is in everything we eat and drink, and is everywhere present, and is probably the principal carrier of the germs of the disease, is more frequently polluted in the country than in the city.

Second. That preventive measures against typhoid fever cannot be successful in cities until a board of health is established in each county, the authority of which shall extend over the whole county, and which shall have a number of active representatives in various parts of the county who will report cases of contagious disease and search for their causes.

The necessity of such a board of health is illustrated by an incident which came to my notice last year. A lady told a doleful story of one of her market-women, who said that she had that day one daughter lying dead from typhoid fever and another at the point of death. And yet this woman came to market with butter, cheese, and other manufactured articles in which was water from her spring or well which in all probability spread the disease in her family.

This is only one of many similar occurrences which inquiry would discover in the markets of Reading.

Third. The Board of Health of the city of Reading, with its present powers and its present methods of work, is of no practical use, beyond being a convenience to the citizens for the abolition of open and glaring nuisances, and the tabulation of births, deaths, and marriages. The contagious-disease records, so long as only one case in four is recorded, are utterly useless for any purpose. It must be said, however, that this fault lies not with the Board, but between the laws which created it and the physicians who are expected to report cases of contagious diseases but fail in three cases out of four. The error in the law lies in its failure to compensate physicians for making out certificates of disease, and there is no reason to expect physicians to do this work carefully without remuneration. A small fee paid for such service would undoubtedly make it much more efficient, but it should be small, to prevent abuse in the other direction. To guard against the issuing of false certificates, the signature of the head of the family might be required in addition to that of the attending physician.

Fourth. All boards of health should possess sufficient money, power, and inclination to push their inquiries beyond mere tabulation of cases of disease; and unless they search for and remove causes of disease their work is of very little value. There are no reasons why an agent of the Board of Health should not follow every case of contagious disease, and examine its environment in every feature—the water- and food-supply, the source of the milk, the condition of the cesspool, and everything which might possibly affect the well-being of the invalid. If this were done, our boards of health would, in all probability, in a few years be able to trace every case of contagious disease to its origin, and, of course, to recommend successful means of prevention.

THE CHEMICAL RELATION OF OZONE AND HYDROGEN PEROXIDE.

BY CHARLES HENRY BROWN, M.D.,
OF NEW YORK.

I HAVE been much interested in the study of ozone and in the investigation of its chemical nature, and have recently, with the aid of Dr. Stanley Wyndham, endeavored to unravel the enigma of why peroxide of hydrogen, H_2O_2, should generate

O_3. This was suggested to me by recent articles on the subject, especially those of Drs. Gibier[1] and Aulde,[2] who both associate ozone with peroxide of hydrogen. Another reason which prompts my presentation of the following chemical *résumé*, is that both ozone and hydrogen peroxide in various combinations are destined to play important, yet different, *rôles* in therapeutics, and it is well to have a correct and practical idea of the nature of these compounds.

"The wonderful properties of ozone are but partly understood; like some other powerful agents, it cannot be safely handled, but it gives great promise in the future. The statement has been made that ozone is but an allotropic form of oxygen, and that it is identical with hydrogen dioxide (the subject of the present article), and for all practical purposes, from a therapeutic standpoint, they may be considered substantially the same." (Aulde.)

"It is worthy of notice that water charged under pressure with fifteen times its volume of pure oxygen has not the antiseptic properties of peroxide of hydrogen. This is due to the fact that when the peroxide is decomposed nascent oxygen separates in that most active and potent of its conditions, next to the condition or allotropic form known as ozone. Therefore it is not illogical to conclude that ozone is the active element of peroxide of hydrogen." (Gibier.)

It is considered that oxygen is capable of three allotropic modifications, viz.:

O_2, ordinary (unactive) oxygen; O_3, ozone; and O_1, active oxygen.

The latter form of oxygen (O_1), which only exists in *status nascendi*, is the most powerful oxidizing agent known, and is capable of combining with inactive oxygen (O_2) and forming ozone (O_3). Ozone is also a powerful oxidizer, in fact not much less so than O_1, and as it is only formed in the presence of O_1, a distinction is in many cases difficult, and the chemical action is often ascribed to ozone, as for instance, as stated above, in the case of hydrogen peroxide (H_2O_2), the oxidizing agent of which is not ozone (O_3), but nascent or active oxygen (O_1).

The following distinctions, arranged according to Baumann,[3] still further show the difference between ozone and hydrogen peroxide, and the relation that O_1 bears to each.

1. Active oxygen combines with inactive oxygen forming ozone, which is easily demonstrated in all cases in which its formation is not inhibited by the presence of easily-oxidizable bodies.

2. Active oxygen oxidizes water, and forms hydrogen peroxide. This does not take place when ozone acts on pure water (*vide* the following experiment).

3. Active oxygen oxidizes the nitrogen of the atmosphere forming nitrous and nitric acids. Ozone has no effect on nitrogen.

4. Active oxygen oxidizes carbon monoxide to carbonic acid; this is effected by ozone.

Positive (O_1) and negative active oxygen (O_1) act essentially in a similar manner. It is certain, however, that the action of hydrogen peroxide (H_2O_2), whose oxygen according to Schonbein is positive, is much less intense than that of ozone, O_3. Ozone is a gas, hydrogen peroxide a liquid, and this fact alone necessitates a different action of the two toward various bodies. In both (apart from the positive or negative electricity, a difference which may be safely assumed) the oxidizing factor is O_1; in the one compound bound to inactive (latent) water, in the other to inactive oxygen. The following tests may suffice to prove the different action of H_2O_2 and O_3 on other bodies, and also serve as a distinction between the two compounds.

If an aqueous solution of a basic lead salt[1] be added to a solution of hydrogen peroxide a reddish-brown precipitate, accompanied by an evolution of gas, is formed. Even in very dilute solutions the browning of the precipitate is perceptible. With aqueous solutions of basic copper salts, a black precipitate of copper peroxide is obtained which soon turns bluish-gray, and finally becomes light-blue cupric hydroxide; if the solution of the peroxide of hydrogen is concentrated an evolution of gas may also be observed. Ozone, on the other hand, effects no change in these two reagents, neither is there any evolution of gas.

A further distinctive reaction is given by chromic acid. If a few drops of a solution of the latter and some ether are added to a solution of hydrogen peroxide, and well shaken together, the solution assumes a beautiful blue color, owing to the formation of perchromic acid, and on allowing it to stand the color is taken up by the ether and a deep blue layer separates out. Even in very dilute solutions of peroxide the blue coloration is still distinctly discernible. Ozone in gaseous form or in solution does not affect the chromic acid.

It has been stated that a solution of ozone in water resolves itself in time into peroxide of hydrogen. To prove that this is not the case, I tested solutions of ozone which were six weeks old, and which had been exposed to the air several times. They still gave all the ozone reactions, but were not affected by chromic acid; if the slightest trace of hydrogen peroxide had been formed, its presence would have been shown by a blue coloration.

Permanganate of potassium is immediately discolored by peroxide of hydrogen, brown oxide of manganese being formed, accompanied by a strong

[1] Gawalowski; Rundschau, 1889.

evolution of oxygen gas; whereas, if ozone is passed through a solution of permanganate of potassium, the latter remains unchanged.

Very interesting is the action of ozone on egg-albumin. If a saturated aqueous solution of egg-albumin (having a very slight yellow color) be treated with ozone, it rapidly assumes a golden-yellow coloration, very similar to the color of undiluted egg-albumin. This ozonized albumin does not coagulate, even when heated up to the boiling-point.

If the same aqueous solution of egg-albumin be treated with hydrogen peroxide, the color is not changed, a strong evolution of gas is observed, and on the application of a slight degree of heat the albumin is coagulated.

It has been established by various investigators that the molecular formula of ozone is O_3. Andrews and Tait[1] demonstrated that ozonization is accompanied by a change of bulk. In the formation of ozone three volumes of oxygen are condensed to form two volumes of ozone, which, when heated, increase in bulk to form the original three volumes of oxygen; whilst, when acted upon by potassium iodide, one-third of the ozone is spent in liberating the iodine, and the other two-thirds go to form ordinary oxygen, thus: $O_3 + 2KI + H_2O = O_2 + I_2 + KOH$. This supposition has been proved to be correct by Soret,[2] as follows: Many essential oils, such as turpentine and oil of thyme, were observed by Schonbein and others to possess the property of absorbing ozone without decomposing it, and Soret showed that the diminution in volume which takes place on the absorption of the ozone by these oils is exactly twice as great as the increase of volume observed when ozone is decomposed by heat.[3] A series of three experiments proved that for every 19.3 c.c. of ozone absorbed by the oil, 9.47 c.c., instead of the exact number, 9.65 c.c., of common oxygen were formed on heating. These various experiments conclusively prove that dry oxygen is converted into an allotropic modification possessing the molecular formula O_3 (ozone), three volumes of common oxygen having been condensed to two volumes by the formation of ozone. In regard to its volume, the molecule O_3 simply obeys the law of Avogadro,[4] by occupying the space of two atoms of H, consequently $3O_2 = 2O_3 = 2(O_2 + O_1)$. In a given quantity of oxygen there is only a small proportion transformed to O_1, a number of molecules of O_2 remain unchanged, and to these the molecules of O_1 attach themselves and form O_3. As, however, the union is effected with but little force, the newly-formed molecule O_3 contains two firmly-bound atoms and one loosely-bound atom, and this latter one can act chemically in a similar manner to a free atom. In oxygen, O_2, each atom is doubly bound to the other $O=O$; in ozone each atom is bound singly to the other, and if a reductive body comes into contact with this lightly-bound molecule, the action is much quicker and more intense than with a molecule of ordinary oxygen. It is due to this single atom O_1 alone that this great activity takes place; O_2 alone, for instance, is incapable of oxidizing indigo to isatin, but O_1 (as contained in ozone) accomplishes this in a short space of time.

$$C_8H_5NO + O_1 = C_8HN_5O_2.$$

It is right to conclude that hydrogen peroxide and ozone are different compound bodies, and that both depend for their great activity upon the availability of the unsaturated atoms of O_1. And the question as to their differences relates to the varying availability of these unsaturated atoms, no matter whether charged with positive or negative electricity, or whether the O_1 is derived from O_3—H_2O_2—Mn_2O_7, or elsewhere.

Ozone, up to the present time, has played but a slight *rôle* in practical medicine. This has been chiefly on account of its not being generated easily and because it cannot be kept long. I have, through the kindness of the Ozone Manufacturing Company, of New York, been able to satisfy my mind upon the fact of the practicableness of ozone, both as ozonized oxygen and in various preparations, and of the marked essential differences that will be found between this body (ozone) and hydrogen peroxide in therapeutics. Each will have its special field of action, and it is only right not to confound one with the other; and to speak of hydrogen peroxide depending upon ozone as the active factor is as erroneous as to say, "Ozone depends upon water in combination to act as an oxidizing agent"; or to say: "If ozone is combined with water it is hydrogen peroxide."

25 WEST FORTY-FIFTH STREET.

NEW PROBLEMS OF NUTRITION IN HEALTH AND DISEASE.[1]

BY A. B. MACALLUM, B.A., M.B., PH.D.,
LECTURER ON PHYSIOLOGY IN THE UNIVERSITY OF TORONTO.

THE use of iron in anæmic conditions is nearly as old as the history of medicine, and it has always been regarded as one of the most precious remedies that we have. Even in popular opinion it has its place, although it has won this position since chemical analysis first showed its presence in the blood-

[1] Delivered as one of the lectures of the Post-graduate Medical Course of the University of Toronto, December 20, 1890.

pigment. How the remedy effected the removal of the anæmic condition was not explained until after the same demonstration.

The first theory worthy of attention was put forward by Fourcroy, who believed the blood-pigment to be a solution of basic phosphate of iron in albumin and that he could form thus the destructive coloring-matter of the blood. Others at the same time described the gradual change to red of the coagulated chyle, when the latter was exposed to the air, and it was further stated by some observers that the chyle from the thoracic duct, especially from that of the horse, undergoes this pigmentation even before its removal from the duct. These observations, although not found correct by skilful observers, among them Johannes Müller, served for a long time as a support to the theory of Fourcroy.

Our more modern theories have not advanced much beyond this one. At the present day the view most prevalent amongst the exponents of medical science is that the iron salts of the food unite with the albumins to form albuminates which, in some way, pass into the system to give origin to hæmoglobin. It was never explained in what way the unstable and weakly-combined iron albuminates became converted into a compound in which the iron is so firmly combined that the chemical tests for the metal fail to show its presence. Still the facts that iron in some form is detectable in the foods and that it is present in hæmoglobin were strong enough to silence almost wholly all criticism of the theory. The advocates of the theory pointed to clinical experience. The administration of iron in ordinary anæmias and in chlorosis has been followed in countless cases by marked and permanent improvement. The cause of these abnormal conditions has been always considered a defective supply of hæmoglobin, and the long-continued dosing with iron resulted in an increase of the hæmoglobin in the blood. These being the facts, no other interpretation than the prevailing one could be heard.

Recently, however, Bunge[1] came forward with another theory, built upon the results of his experiments on the nature of the iron-holding compounds in the yolk of the hen's egg. As this theory is, in my opinion, destined, in a modified form, to supplant the one just described, it is worthy of an extended description here. It is well known that the hæmoglobin of the blood of the chick is formed out of compounds present in the yolk. What these compounds are no one knew until Bunge analyzed them. On the basis of the older view the yolk was assumed to contain an inorganic iron salt. Bunge, by methods which I need not describe, isolated an iron-holding compound of the nature of a proteid, but containing phosphorus and therefore belonging to the group called nucleins. Like the latter it does not dissolve in gastric juice; in other words, it cannot be converted into peptone, and it dissolves in alkaline solutions, from which it may be precipitated by acids. Its iron is not removable by the hydrochloric acid of the gastric juice, and is only so separated when the acid solution is considerably more concentrated. The ordinary alkaline sulphides, such as ammonium sulphide, attack the compound and separate the iron as sulphide when both are kept at or near body temperature for several hours. This iron-holding nuclein Bunge called hæmatogen because he considered it to be the substance out of which the chick's hæmoglobin is produced, and as he determined the existence of similar iron-holding nucleins in milk, and in that part of our food furnished by the cereal and leguminous plants, he concluded that the hæmoglobin of the blood of all animals is directly or indirectly derived from the iron-holding nucleins of the vegetable kingdom. In the animal body these compounds are assimilated in some way and the assimilated product appears as hæmoglobin.

The benefits obtained from the exhibition of iron in simple anæmia and chlorosis are explained by Bunge in the following manner:

In ordinary anæmia, for example, there are in the intestine more or less putrefaction and fermentation due to lack of digestive vigor on the part of the stomach, which permit, therefore, a freer entrance of bacteria than in health. In this putrefaction alkaline sulphides are formed; these act on the iron-holding nucleins and separate their iron, which is excreted with the fæces as sulphide. If, however, sulphides are abundant, all the hæmatogens are decomposed, their iron is removed, and the system consequently deprived of the usual supply of that compound necessary for the formation of hæmoglobin. Should this condition continue long enough the results are a marked diminution in the quantity of hæmoglobin and an asthenic condition due to the deficient respiration of the tissues. Could these sulphides be decomposed and rendered inert in some way, the hæmatogens might be saved for assimilation and the anæmic condition thereby removed. Iron and iron-salts readily effect this decomposition by combining with the sulphur of the sulphides, and if administered in large quantities the whole of the alkaline sulphides is thereby disposed of. The hæmatogens, which are thus protected from decomposition, can consequently be absorbed as such, and as the digestive and secreting vigor of the stomach gradually returns with the increase in the amount of hæmoglobin in the blood, intestinal putrefaction is diminished and the alka-

[1] Zeit. für Physiol. Chemie, Bd. x. p. 49.

line sulphides cease to be formed in considerable quantities. In Bunge's view, therefore, the administration of iron to anæmic and chlorotic patients is for the purpose of protecting the iron-holding nucleins from decomposition.

Sometimes the administration of hydrochloric acid, without any iron at all, removes the anæmic condition, and Bunge believes that this happens especially in those cases in which the gastric juice is deficient in quantity and therefore feebly germicidal.

In support of Bunge's theory it may be considered as established that the whole or nearly the whole of the iron salts administered with the food passes out with the fæces as sulphide. Furthermore the most careful experiments of Hamberger[1] show that iron-salts given in the food are not assimilated into the system, and consequently it is improbable that there can occur in animal tissues a synthesis of hæmoglobin from iron salts and a proteid or proteids of the food.

It may be urged that the synthesis of an iron salt and a proteid may take place in the body, and yet the facts in support of this may be so difficult of access, that experiments in the chemical or physiological laboratory may not show them. Again, since the amount of iron in the blood of an adult individual averages 3 grammes, and since in health the amount of iron in the urine—assuming this to be the only mode of excretion[2]—is from 3 to 5 milligrammes daily, it is obvious that if inorganic salts are absorbed by the intestine to make up for this loss not more than 1.5 grammes of the metal are so utilized in a year. Now this quantity is so small as to be beyond estimation, when one has to take into account that in a year an enormous quantity of food is ingested and a large quantity of matter excreted as fæces and urine. In fact the errors of experiment would be vastly greater than 1.5 grammes. This objection is, I think, well taken, and unless it can be shown that such absorption of inorganic iron compounds is unnecessary or contrary to our knowledge of animal metabolism, it will be fatal to Bunge's theory.

We must, therefore, turn to the teachings of biology on this point. It is a well-known fact that plants cannot grow without access to iron salts in the soil. If a plant is reared in a solution containing all the other chemical ingredients necessary for its nutrition, but absolutely free from iron compounds, it is completely colorless; in other words, it fails to develop the green coloring-matter which is generally credited with the power to build up, under the influence of sunlight, starch from the carbon dioxide of the air. It was at first suspected from this that the iron entered into composition with the chlorophyll, or was associated with the latter in some way. Such a connection, however, has never been observed, and all solutions of chloropyll are free from iron. What is done with iron in the vegetable cell was not known until the results of Bunge's researches were published. We now see that it is united with the nuclein so firmly that the ordinary tests for it fail to reveal its presence. There can, therefore, be no doubt of the absorption and assimilation of iron by the vegetable organism. Indeed, one can see this clearly when one strokes a bleached plant grown in an iron-free solution, with a glass rod moistened with a weak solution of an inorganic iron compound. Some hours after doing so there is along the line of the streak a green color, showing that, in that time, the cells have so vigorously absorbed iron as to enter on their full functions.[1] Now the absorption of iron is so prominent in plants that we may say it is a special vegetable function. We are, moreover, in the habit of drawing broad lines of distinction between vegetable and animal metabolism. We say that the vegetable-cell builds up chemical compounds out of simple chemical substances, and stores up energy from the sunlight, and in contrast that the animal cell decomposes the same compounds and derives therefrom its energy. In the animal-cell any formation of complex compounds out of simple chemical compounds is impossible. It is true there are views current that fats are partly derived in some way from the starchy part of food, but these views cannot be held to vitiate the conclusion already given until it is finally and definitely shown that the absorbed carbohydrates of the food do more than protect from decomposition the fats derived as such from the foods, or the fats obtained by metabolism from the proteids of the food or of the body. Now, if construction of complicated chemical compounds out of simple ones is a function of the vegetable-cell, while the animal-cell decomposes the same compounds, but does not build up, why should we make an exception as to the formation of iron-holding proteids in the case of the animal-cell? We know that in hæmoglobin the iron is very firmly combined, and it is even as firmly combined in the

[1] Zeit. für Physiol. Chemie, Bd. ii. p. 191.

[2] There are other channels for the excretion of iron. It is admitted that the bile contains iron compounds and it is furthermore shown in experiments in which animals are given iron-salts subcutaneously that the intestinal mucosa functions as an iron-excreting organ.

[1] Recent experiments and observations have rendered it extremely probable that it is the nuclear material in vegetable-cells which is the principal agent in the formation of carbohydrates out of simple substances, and that the carbohydrates so formed are passed from the nuclein to the chlorophyll grains, where they appear as starch. The inference from this is that the iron absorbed is fixed in the nuclear substance. See, on this point, Strasburger, Ueber Kern und Zellthilung, January, 1888, p. 194.

iron-holding proteids from the seeds of various plants. Why not say at once, as Bunge has done, that the hæmoglobin is derived from iron-holding proteids of the vegetable kingdom, sometimes directly, sometimes remotely?

There are a number of facts which tend to show that the broad distinction between the metabolism of the animal and that of the vegetable-cell holds good with regard to the iron-holding proteids. One fact is that obtained by a study of the transferrence of iron from the maternal organism to the egg in fish, amphibia, reptilia, and aves, or from the mother to the fœtus in mammalia. Bunge's hæmatogen is a compound carefully and elaborately prepared long before fertilization takes place, and as such it is deposited in the yolk-spherules of the egg. In other words, the embryo receives its supply of iron in the form of an iron-proteid compound, and it passes a certain part of its existence fully supplied from this source with all the iron it requires. Bunge has, furthermore, shown that the newborn mammal starts into the world with a larger quantity of iron in its body per kilogramme of weight than the older animal has. According to this observer, the iron of milk, the food of the suckling, is firmly combined with a nuclein. I may mention, too, that experiments and observations, such as those of my own, to be described further on, indicate, in the cat at least, that the maternal tissues transfer to the fœtus or embryo not an inorganic iron compound, but an iron-holding proteid. It is thus seen that the developing animal-cell or organism is carefully provided by the maternal organism with a supply of a firm, stable, iron-holding proteid, and that it receives iron in no other form. On the other hand, the vegetable ovum receives just so much iron as will enable it to develop chlorophyll enough for its seed leaves, after which its embryonic root furnishes by absorption all that is needed for its future growth. There is, therefore, a great difference between animal and vegetable organisms on this point. The vegetable-cell has manifestly and preëminently the capacity to combine iron with proteids, and it is equally manifest that the animal-cell, if it has this capacity, leaves it in abeyance in the embryo and in the suckling animal. The question now is, whether the cells of the adult animal have this capacity, and if so whether they use it. The treatment of anæmia and chlorosis seems, as already pointed out, to give an affirmative answer to these questions. The answer, however, is not quite satisfactory, for it must be noted that it is only in large doses that iron is effective in removing the anæmic condition, while only from 3 to 5 milligrammes are absorbed and assimilated in health, assuming that the 3 to 5 milligrammes daily excreted in the urine represent the total amount of the iron derived from the disintegrated hæmoglobin of the body. Is it to be supposed that even a very much greater quantity of iron, in the form of inorganic salts, is wanting in the food of anæmic patients? If the system is capable of building up iron-holding proteids, why is not this large quantity of inorganic iron compounds absorbed and assimilated in anæmic patients as it is, supposedly, in healthy individuals? Is the fault to be found in a lessened capacity of the system to absorb iron salts? If so, what explanation of this lessened capacity can be given? The current view as to the cause of anæmia is that there is too little of any iron salt in the food for absorption, an explanation not firmly founded. If there is too little iron in the food how comes it that in some patients chlorosis may disappear without the administration of iron salts at all, or that in others it may be removed by the administration of hydrochloric acid alone?

We are, therefore, driven back to Bunge's theory for the explanation of the mode of the absorption of iron in health, and of the action of iron salts administered to anæmic patients. Now it must be acknowledged that as far as it goes the theory is the most satisfactory one yet offered to explain the facts. I use the phrase, "as far as it goes," advisedly, because my own researches and observations show that the theory must be considerably extended to cover all the phenomena which they present. These researches were begun five years ago, and they have been carried on with varying intermissions up to the present time. So definite have the results obtained from them lately appeared to us that I thought a connected description worthy of publication, and I have chosen this occasion for explaining them, for discussing the bearings which they have on our knowledge of nutrition, and for putting forward explanations of my own as to the nature of certain diseases.

All of these researches bear on the chemistry of the animal-cell, and, as cytologists have always known more about the structure of the latter than have physicians, it may be interesting here to connect the plain facts of structure with those of composition. The animal-cell usually contains two different morphological elements, the cell-body and the nucleus. The cell-body contains what is usually termed protoplasm, but this is by no means a simple compound, for from it can be obtained albumin, globulin, albumoses, fatty compounds, and glycerin, while its membrane, as well as that of the nuclein, is formed out of a compound called plastin. Now, disregarding the non-proteid elements, we may say that the cell-body is generally made up of proteids, which are like one another in percentage composition, and which are mainly distinguishable from one another by precipitation-tests. In the nuclein, on the other

hand, there are present like proteid compounds, with a peculiar substance which is called *chromatin* by cytologists and *nuclein* by physiological chemists. The term chromatin has been given to it owing to its special affinity for staining reagents. It is sometimes more or less diffused through the nucleus, but usually it is in the form of small granules or clumps called indiscriminatingly nucleoli. When, however, the quantity of chromatin in a nuclein is increased beyond a certain point the nucleus and the cell pass through a series of structural changes grouped under the name karyokinesis, or cell-division, in which the chromatin plays a very important part. The nuclei of the two newly-formed cells have each exactly half of the chromatin of the original nucleus, and when the so-formed nuclei have increased their amounts of chromatin again up to a certain point the same series of phenomena occurs, resulting in the formation of new nuclei and cells. We may turn to other facts to illustrate the importance of chromatin for the life of cells. For instance, it is well known that the greater part of the substance of the head of spermatozoids is composed of chromatin, and it is chromatin only which is transferred to the ovum as the fertilizing agent. It is, in other words, the carrier of those qualities of the male parent which appear in the offspring. The vigorous embryonic cell, according to Minot, is rich in nuclear material—chromatin—while it is poor in cell material. The cells in the old individual present the opposite condition—the cell-material is large, the nucleus correspondingly small. We may say, then, that, other things being equal, the most vigorous cell is the one whose nucleus contains the largest amount of chromatin.

I have already said that the physiological chemist terms this substance nuclein. The latter name was given to it before it was generally thought by cytologists that there could be a specific element in the nucleus. It was isolated from the nuclei of pus-corpuscles, from semen, from the testicles, ovary, etc., and it was found to possess in addition to carbon, hydrogen, oxygen, nitrogen, and sulphur[1]—elements present in ordinary proteids—the substance phosphorus. Now, although nuclein is derivable from chromatin, I do not think the two are identical. In fact, I shall give reasons further on for regarding the nuclein molecule as merely the skeleton of the chromatin molecule. This is readily intelligible when one considers the thorough methods and the strong reagents by which the nuclein is usually prepared. It must also be remembered that if the chromatin is, as Pfitzner calls it, the ground-substance or physical basis of life, chemical changes are ever occurring in it, so that the chromatin compounds in two adjacent cells in the body may have quite different atom-groups tacked on to the molecule-chain. The nuclein, isolable from these two cells, however, would be either a mixture, or a compound very unlike the two chromatin substances which make all the differences in the life of the individual cells.

That this chromatin substance is different from the nuclein of Miescher and others I will now proceed to show.

In the summer of 1885 I observed certain staining-reactions in the nuclei of the red blood-cells of *Necturus lateralis* which were quite different from anything that I had ever seen before. At the time, I believed the peculiar staining-reactions to be due to a substance in some way or other connected with the production of hæmoglobin. A full opportunity to study the phenomena did not present itself till the following spring, when I obtained a number of *Amblystoma* larvæ, which I used in the investigation of this problem. I found that in the hæmatoblast the chromatin was excessively abundant, and just as the chromatin diminished in quantity in the developing red cells so the hæmoglobin increased.[1] I found, moreover, that the hæmoglobin is derived in the same cell from a substance which is diffused out of the nuclear chromatin, and even out of the chromatin loops of the dividing hæmatoblast. The conclusion then adopted was that the hæmoglobin is formed from the chromatin. Support for this conclusion was at that time found in the fact that Bunge had recently isolated an iron-holding nuclein, and in the fact that if the hæmoglobin is derived from the chromatin we may explain more readily the absence of a nucleus in the red blood-cells of mammalia, on the ground that the greater part of its chromatin is transformed into hæmoglobin, and that therefore, the necessity for a chromatin-holding organ is done away with.

During the next year I continued my studies on the origin of hæmoglobin in larval *Amblystomata* and in the spleen of adult *Necturi*, and in the following spring I definitely formulated the view[2] that hæmoglobin is derived from chromatin. *In other words, the chromatin of the hæmatoblasts must contain iron.*

I had in mind the fact that Bunge's hæmatogen is a nuclein. The question now arose, Are there nucleins which are not derivable from the nuclear chromatin, and what is their origin? The hæmatogen of Bunge is deposited in the yolk of the egg, not in its germinal vesicle, and if the latter has not, at any stage of its history, anything to do with the formation of hæmatogen it might be said that in the

[1] Some of the nucleins have been shown not to contain sulphur.

[1] This was previously noticed by Flemming and others.

[2] Presented as thesis for the degree of Ph.D. in the Johns Hopkins University.

developing hæmatoblasts of *Amblystoma* larvæ the hæmatogen of Bunge passes from the yolk-spherules to the nuclear chromatin, to be there converted into hæmoglobin, without the transformation of any of the chromatin itself into the pigment. In that case the presence of iron or iron-holding compounds in the chromatin would be merely a special case, and not of general significance. I studied the genesis of the yolk in the ovarian ova of *Necturus* and came to the conclusion that the nuclein present in the cell of the ovum is derived by diffusion from the abundant chromatin of the nucleus of the same ovum. That the nucleus of the developing ovum gives something to the yolk was already apparent from the observations of Scharff, Will, and Sheldon, but these investigators did not determine definitely what is so given. As Bunge found only one nuclein in the yolk it is very probable that his hæmatogen is the same as the chromatin diffused from the nucleus of the ovum.

Again, Bunge found the nucleins of milk to contain iron, and, therefore, to belong to the hæmatogen group. We know, from the researches of Nissen and others, that the cells of the secreting tubules of the mammary gland, after they have passed a series of changes resulting in the formation of fat-globules and the ordinary proteids of milk, break down, their nuclei undergo degeneration, and the chromatin is cast out into the contents of the lumen of the tubule to constitute apparently the milk-hæmatogen of Bunge.

In 1886 Zaleski isolated from the nuclei of the liver-cells of various animals a substance somewhat like Bunge's hæmatogen, but differing from the latter in that it holds the iron combined in itself much more firmly. This compound Zaleski evidently thought peculiar to the liver-cells, for he names it *hepatin*. It is probably the true chromatin of the hepatic nuclei. Owing, I suppose, to the fact that the liver is generally regarded as a blood-forming organ, and that, therefore, it is possible that one or more stages in the transformation of hæmatogens, or of iron-holding proteids into hæmoglobin, are passed in the liver, Zaleski apparently thought it quite natural that such iron-holding proteids should be found here.

(*To be concluded.*)

A CASE OF HYSTERICAL DEAFNESS.

By H. V. WÜRDEMANN, M.D.,
OF MILWAUKEE.

THE literature of hysteria is very extensive, but though hysterical deafness has long been noticed, very few cases have been reported, and the subject has not been as thoroughly investigated as other phases of this omnivagant disease. The case here reported is somewhat unique from the fact that the general sensation was impaired upon both sides to about an equal degree, and because there existed at the same time an intercurrent disease, which, at first, was sufficient to produce the ear symptoms, and to obscure the diagnosis.

Miss F. S., of German birth, was sent to me by Dr. Wahl on April 29, 1890, on account of interstitial keratitis and deafness; the latter affection was of two weeks' duration, and arose from a severe cold. The eye-trouble has existed for years, and the patient has well-developed Hutchinson's teeth. She is well nourished and somewhat stupid. Speaks both English and German. She was treated for "chorea" about two years ago.

She had well-developed catarrhal otitis media in both ears, and the secretion could be seen through the drum-membrane of the right. Hearing distance, right ear, by the watch, 8 cm.; left, 75 cm. (normal 150 cm.). The left ear was cleared by catheterization, but the fluid could be removed from the right tympanum only by paracentesis of the membrane. After the fluid was removed, hearing distance, R. $= \frac{15}{CL}$; L. $= \frac{120}{CL}$. It was noted at the time that the patient did not seem to feel the needle, but no investigation was made in regard to it. The ordinary treatment was used for the eye, and the ears were inflated by the Politzer bag several times until May 7th, when she complained that she was unable to understand the speech of the members of her own family, and her father, who came with her, corroborated this statement. She seemed to hear and understand everything that I said both in English and in German. The hearing seemed to be again increased by the use of Politzer's bag, but the watch could not be heard.

The next day she asserted that she was totally deaf. She could hear the voice, but could not distinguish any words. The low-pitched tuning-fork could be heard through the ear but not through the bone, and the fork of high pitch could not be heard at all. This condition corresponds with the statements of others in reference to hysterical deafness,[1] and first led to the suspicion of the true condition. The objective symptoms of the catarrhal inflammation seemed very slight, and the Eustachian tubes were open to Politzerization. There were areas of anæsthesia and analgesia embracing parts of the pinna, the auditory canals, and the drumheads of both sides in the same degree. The prick of a pin in the canal and the touch of a probe upon the drums gave rise to no pain. On her knees, feet, and hands sensation was lessened as far as could be ascertained from the patient, whose perceptive faculties seemed to be even more dulled, and who was evidently frightened by her symptoms. The knee-jerk seemed normal. The application of a magnet was tried as a means of diagnosis, as is recommended by several writers,[2] but as suspected without result. The electric current was also used with like result.

[1] G. L. Walton: Hysteria, Ref Handbook Med. Scien., vol. iii. p. 803.

[2] Politzer: Ohrenheilkunde, p. 520. Gruber: Ohrenheilkunde, p. 632.

The treatment adopted was mainly calculated to produce an impression on the patient. It consisted in the use of a sufficiently strong current of galvanic electricity to the ears and nape of the neck to produce a decided burning sensation. A blister was applied to the nape of the neck and the mastoid processes. The use of hot baths at night was recommended, and the previous alterative and specific treatment for the eye and ear was continued.

Three days later she could hear and understand words spoken in German, but not in English. The next day both languages were plainly understood, and the hearing-distance, by the watch, was R. = P (pressure of watch upon meatus); L. = $\frac{5^{0}}{CL}$. The patient was seen several times, and the previously-described treatment was used. She discontinued treatment some two weeks later, when conversation in both German and English was easily understood, and hearing-distance was R. = $\frac{3^{0}}{CL}$; L. = $\frac{15^{0}}{CL}$. The areas of diminished sensation persisted on either side, but in less degree. The membranæ tympani were restored to their normal appearance.

805 GRAND AVENUE.

CLINICAL MEMORANDUM.

OPHTHALMOLOGICAL.

A Case of Traumatic Paresis of Accommodation.—On the evening of July 6, 1890, Dr. W. was struck in the face by a boy from whom he was pulling a tooth. The blow glanced upward along the right side of the nose and reached the right eye with considerable force. For two hours the eye was painful; but after the pain ceased the circumstances of the injury were forgotten and not called to mind until four days later. On the day following the injury the upper lid was swollen, red, and sore. This condition slightly increased for four days, and extended into the cellular tissue around the eye. Pressure produced some pain, and the patient feared severe orbital cellulitis, but an unusual amount of work prevented him from receiving appropriate treatment. A few applications of liquor plumbi subacetatis, ½ drachm to 6 ounces of water, were made without much apparent benefit.

On the morning of July 11th Dr. W. noticed blurred vision of the right eye when looking at near objects. I examined the eye with an ophthalmoscope and by oblique illumination and found no evidence of iritis. The pupil was in no respect different from that of the other eye. One drop of eserine sulphate solution, 2 grains to an ounce of water, was instilled into the eye. The dimness of vision and symptoms of cellulitis diminished during the day. At night another drop of eserine solution, ⅔ grain to the ounce, was dropped into the eye. A weaker solution was used because the drop instilled in the morning produced strong, spasmodic contraction of the pupil.

The patient experienced no further trouble until the morning of July 13th, when he found that distinct vision for near objects was entirely gone in the injured eye, and great dilatation of the pupil—a mere rim of iris, $\frac{1}{16}$ or $\frac{1}{12}$ inch broad, remaining. For distance, V.=$\frac{6}{IX}$(Sn.), equal to that of the other eye. All symptoms of cellulitis had disappeared.

One drop of the weaker solution of eserine contracted the pupil and restored the power of accommodation. No further treatment was adopted, except the use of colored spectacles and rest. Slight paresis of accommodation returned after the effects of the eserine subsided; but this gradually wore off.

IDA R. GRIDLEY, M.D.

COLLINSVILLE, CONN.

ORIGINAL LECTURES.

A REPORT OF SIX CASES TREATED BY KOCH'S LYMPH FOR THE CURE OF TUBERCULOSIS.

A Clinical Lecture
delivered at the Philadelphia Hospital, January 28, 1891.

BY ERNEST LAPLACE, M.D.,
PROFESSOR OF PATHOLOGY AND CLINICAL SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE; VISITING SURGEON TO THE PHILADELPHIA HOSPITAL, ETC.

[Reported by W. BLAIR STEWART, M.D.]

GENTLEMEN: I am under obligations to Professor Anders for the use of his hour this morning that I might present to you a few cases which have been treated in the hospital by Koch's lymph. In entering upon the subject, I take it for granted that you consider the question from the same point of view as I do, namely, that the tubercle bacillus is the cause of the development of tuberculosis; it develops at the expense of the tissues, liberating an irritant which causes a proliferation of the cells. These soon disintegrate, necrose, and change from a hyaline to a milky or cheesy mass. The cells have undergone fatty degeneration or coagulation-necrosis, as it is called, break down and, when in the lungs, form a cavity. This is the case where there are epithelial cells. The same occurs in fibrous tissue; the soil being different, the seed remaining the same. This was first proved by Koch in 1882, when he demonstrated the existence of the tubercle bacillus. He not only found, isolated, and stained the bacillus, but inoculated animals with it and always produced the same disease. I tell you this, so that you will understand that he did not stumble on the discovery; it was the outcome of eighteen years of hard and faithful study which finally culminated in extracting from the bacillus itself that substance by which he is able to destroy tuberculous tissues.

If any one of us were placed under such conditions that we had to reabsorb the urea produced, or breathe the carbonic acid gas from our lungs, we would soon die from its effects: so the germs die if they have to live in their own waste-products or, as we call them, *ptomaïnes*. Three years ago it was well known that Koch had been working constantly and had found something that would prevent tuberculosis in animals but with his modesty, he withheld the facts until he was forced to publish them by the Minister of Public Education of Germany. Until a few days ago, I could only surmise what the fluid he had discovered might be, but now we have had, as you know, a description of its preparation from Koch himself. Having isolated the tubercle bacilli, he cultivated them in artificial media—agar-agar or blood-serum and glycerin—collected them

and inoculated healthy guinea-pigs with the result that they contracted large ulcerated tuberculous patches, known as lupus, and ultimately died of the disease. Inoculating guinea-pigs that were suffering from tuberculosis with the same culture he found that there was no reaction.

The question then arose in his mind, if these are the results obtained with living cultures, what would be the result with dead cultures? He destroyed the same cultures with heat and antiseptics, injected some of this dead material into a healthy guinea-pig but did not get any reaction. He then injected it into a tuberculous guinea-pig with the result that the reaction was so strong that the animal died from dyspnœa in a few hours. All tuberculous guinea-pigs died within a few hours after an injection of a large dose of this dead culture. If this be the result with large doses, what would be the effects of smaller ones? Instead of giving one gramme he gave one one-thousandth of a gramme and found that the guinea-pigs lived and got better. He repeated the dose and the improvement was so great that the animals recovered. Here lies the foundation of the system we are now investigating. Therefore, we must give a small dose to know the effect; and, under these small doses, regional tuberculosis is checked.

We must divide our cases for study and treatment into two classes, viz.:

1. External or surgical tuberculosis, which comprises lupus—tuberculosis of the skin—and tuberculosis of the joints.

2. Internal or medical tuberculosis, including tuberculosis of the lungs and of other internal organs.

CASE. I.—Here is a woman who has had lupus involving her entire face, and her neck and back for more than forty years. It is now two weeks since we gave her the first injection. The remedy caused a chemical reaction that produced decomposition on the surface of the ulcers. In this case we were warranted in giving a larger dose than if the disease were internal, and within the two weeks of treatment the ulcers have healed. We proceeded about in the following manner: We gave five milligrammes and found that it caused a slight reaction. On the second day, we gave a larger dose and got more reaction. After this we gradually increased the doses until she received ten times the first dose, when the temperature rose to 102.5° F., and fell on next day to 99°.

Two days ago we gave her twenty-five times the original dose and scarcely any fever resulted, showing that, in spite of the increasing doses, the system was saturated with the material. I will now inject her with one hundred times the first dose to determine if she has received enough.

In order to preserve the lymph from decomposition when diluted, it is necessary to add one-half per cent. of carbolic acid.

CASE II.—Here is an interesting temperature-chart of this patient, who has been suffering from tuberculosis of the apex of both lungs, and also from hip-joint disease. He had a tubercular abscess with a number of sinuses for years. On one occasion it closed but soon reopened. Under injections of the lymph these sinuses and abscesses have closed, and he has shown signs of great improvement. Being a case of lung tuberculosis, as well as surgical, we were not warranted in giving him a large dose, which would excite inflammation about the tuberculous deposits and, if sufficient were given, would cause a violent pneumonia from which the patient would die—not from the lymph but from the pneumonia. We began treatment in this case with one milligramme and gradually increased the dose to three centigrammes, when his temperature rose to 104⅘° F. Finally we thought it best to let him rest for three days and then injected four centigrammes which caused an elevation of temperature to 104° F. An interesting fact in this case is that he was not very tuberculous and did not begin to react until he received two centigrammes. As soon as reaction to any degree takes place the temperature sinks below normal. As the patient has not reacted very much we know that his system is not saturated, and it will not be saturated until he ceases to react as the first case has done.

CASE III.—This boy has tuberculosis of the leg, knee, and ankle-joint. We began treatment by injecting one milligramme, then increased to five milligrammes, and later to one centigramme, when he reacted with a temperature of 104° F. Three centigrammes caused a temperature of 105° F.; six centigrammes 104.6° F. and this morning his temperature was normal. As far as the improvement in this case goes, the only thing we notice is that the dull, glazed, dirty surface of the ulcer has cleaned off and is assuming a healthy appearance. As far as the limb is concerned, the time is still too short to notice any great improvement, as in the case of lupus. The sinuses have swollen and a certain amount of serum and a piece of necrosed bone came from them, showing that a violent reaction took place. Should the tuberculous process in the bone be near the surface it would have separated more readily. The reaction in bone is the same as in other tissues, but the ability to heal is different in deep-seated lesions. At the last injection he received six centigrammes, and to-day we will give him ten centigrammes of the pure lymph.

CASE IV.—Here is an interesting case of a negress who had swollen glands in her neck and a peculiar eruption on her body that could not be positively diagnosed. In her case we tested the value of the lymph as a method of diagnosis. The day before it was used, her temperature was 104° F., while at the time of the injection it was 101° F. The lymph was used on alternate days and produced the characteristic rise of temperature that we would expect in a case of tuberculosis when treated by this method. After the injections the glands began to swell and became tender and sore, but assumed a normal appearance when the reaction passed off.

CASE V.—This man is the only case of tuberculosis of the lungs that we have treated with lymph in this hospital. For three years he has had a cough and we have demonstrated consolidation of the apex and the presence of bacilli in his sputum. After a dose of one milligramme he reacted, his temperature rising to 101⅘° F., and falling on the next day to 98° F. The second dose was two milligrammes, his temperature rising to 102° F.; a dose of five milligrammes caused a rise to 102.5° F.; twenty milligrammes to 102.5° F.; forty milligrammes to 103° E.; sixty milligrammes to 103.8° F., followed by a fall to 98.5° F. After the last dose the temperature rose to 100° F., showing that under increasing

doses the temperature does not rise so high and that the system is saturated with the lymph and the tuberculous tissue destroyed, He has not lost flesh, has a good appetite, and says that he feels better than at any time since he was first taken sick.

Case VI.—Here is a young man who comes to receive for the first time treatment for tuberculosis of the lungs. There is consolidation at the apex of each lung, and numerous bacilli in the sputum. Professor Koch wishes that no cases of tuberculosis of the lungs be treated at first with larger doses of the lymph than one milligramme, as this amount will serve as a guide as to the strength of future doses. If the patient does not react by the second day we will give him five times the original dose. If he should react strongly we will give twice or three times the dose.

From what I have said, it is evident that the lymph acts as an irritant. If used pure, under the skin, it would cause sloughing, but when diluted it is taken into the circulation and does not cause the local effects. The strongest argument against the identity of scrofula and tuberculosis is the fact that the tubercle bacilli are around the cheesy, degenerated mass and not in it. The reason the bacilli are not found in the middle of the mass (the understanding of this fact gives us the keynote of the Koch treatment) is explained thus: When the gland began to be diseased it contained epithelial cells; these cells were irritated by the bacilli, proliferated, and caused the gland to enlarge and degenerate or become white and cheesy. Just as these cells were destroyed, so the bacilli were killed by their own refuse matter. The bacilli can exist only where the proliferation is still going on; this is the reason we cannot find them in the cheesy masses. Koch found that by injecting the lymph into the tissues it was taken up by the blood, and caused the same condition in the tissues throughout the body, which would destroy the bacilli and induce necrosis of the diseased tissues.

Great care is to be taken in administering the lymph, for inflammatory reaction is certain to follow the injection. Should too much lung-tissue, or other tissue essential to life, be affected, the reaction would necessarily hasten a fatal result.

The French claim that the treatment gives rise to albuminuria and hæmaturia, but the cases cited by them may have been unsuspected tuberculosis of the kidney or bladder. Two weeks ago none of us suspected that the first case I showed you had lupus on her forehead, but after the use of the lymph a red spot appeared on the forehead and a distinct reaction took place there, showing that the germs were present. In one case in Europe a boy was inoculated, after which there appeared a patch of redness on his nose, indicating a process that would have ultimately caused lupus; this was not suspected before inoculation.

The contra-indications for the use of the lymph are—

1. *Extensive tuberculosis of the larynx*, unless you have taken the precaution to perform tracheotomy previously or are holding yourself in readiness to do it at a moment's notice.

2. *Acute miliary tuberculosis.* A few months ago I treated a man for fistula in ano. He came to me a short time ago to be treated with the lymph. I found his temperature 104° F., and crepitant and subcrepitant râles in his lungs, and diagnosed acute miliary tuberculosis. I think he would have died under the first injection, had it been given to him. At present he is running the characteristic course of the disease.

3. *Tubercular meningitis*—from the necessary reaction in the brain that would follow the injections.

You may ask if I have seen cures. Out of the two thousand cases that I saw in Berlin, I cannot say that I have seen one case positively cured, but I have seen great improvement. I cannot speak of the improvement as a cure, but can now only confine myself to clinical facts, inasmuch as a year at least would be required to pronounce a case as permanently cured.

There may be a possibility of aggravating and disseminating the disease by the lymph, but there is nothing to prove that these results occur. In five cases that died under the use of the lymph, the autopsy showed that in each case death was due to pneumonia produced by the irritation from the reaction, and no new foci of infection could be detected. I have seen a case like the woman with lupus that was discharged as cured; three weeks later some tubercles reappeared, but under treatment again promptly disappeared. I think we can draw the following conclusions:

1. Koch's lymph is a valuable means of diagnosis, as a non-tuberculous person will not react under its use.

2. It is destructive to tuberculous tissue, and acts more effectively on tuberculosis of the surface of the body than elsewhere from the possibility of the diseased tissue being shed.

3. The results obtained so far warrant us in using it to establish further its real merits.

4. We cannot restore destroyed lung-tissue, but if we can prevent tuberculosis in the beginning—that is, change the tuberculous soil of the patient, we could soon have the disease under as complete control as smallpox is to-day. In fact, when the irremediably-affected persons would die we could almost eradicate the disease.

MEDICAL PROGRESS.

Gargle for Tonsillitis.—The *Gazette Hebdomadaire des Sciences Médicale* gives the following gargle as a useful one in tonsillitis:

℞.—Metallic iodine		1½ grains.
Iodide of potassium, Tannin	of each	15 to 45 "
Water		2 ounces.

To be used as a gargle three times a day.

Lotion for Favus.—Kaposi recommends the following lotion in the treatment of favus:

℞.—Carbolic acid		75 grains.
Glycerin, Alcohol	of each	1 ounce.

After allowing this solution to remain on the part for twenty-four hours, and upon the removal of all hair, the head is to be washed twice a day with green soap. Aftes each washing the lotion should be reapplied.

Application for Cancer of the Uterus.—According to *L'Union Médical*, Braun recommends the following

mixture to be applied to carcinomatous ulcers of the uterine cervix.

℞.—Bromine . . . . 30 grains.
Alcohol . . . . 2½ drachms.

The surrounding parts should be protected by tampons. After the application the surface is to be covered with absorbent cotton, sprinkled with benzoate of sodium. At the same time narcotics are to be given internally to relieve the pain and insomnia. For the relief of vomiting pieces of ice or gaseous waters or small quantities of cherry-laurel water may be administered. Disinfecting vaginal injections composed of chlorinated lime, thirty grains to two drachms to a pint of water, should be given.

Prescription for Hæmoptysis.—DE MOUSSY recommends the administration of the following pills for hæmoptysis:

℞.—Powdered ergot, Powdered extract of rhatany } . 1 drachm.
Extract of belladonna . . 5 grains.
Powdered digitalis . . . 10 "

Make into forty pills and give from four to six at a time. Insist upon the patient's remaining in bed, apply heat to the extremities and allow the patient to swallow small pieces of ice.

Calmative Mixture for Hysteria.—According to *L'Union Médical*, GRASSET employs the following prescription in hysteria:

℞.—Chloral, Bromide of sodium } of each 1 drachm.
Extract of belladonna . . ½ grain.
Extract of cannabis Indica . ½ "
Syrup of acacia . . . 2 ounces.

Of this mixture from one to four teaspoonfuls may be given. If one teaspoonful is given it may be repeated every half-hour or hour until eight doses have been taken.

The dose may be placed in a tumblerful of infusion of orange-flowers. If pain is associated with hysterical insomnia antipyrine may be given, and it is well to administer arsenic, if the mixture, just mentioned, containing bromide, is used for any length of time.

Powder for the Treatment of Hay-fever.—*L'Union Médical*, January 10, 1891, gives the following prescription for the treatment of hay-fever.

℞.—Powdered boric acid . . . 30 grains.
Powdered salicylate of sodium . 35 "
Hydrochlorate of cocaine, finely powdered . . . . 1 grain.

This powder is to be snuffed up into the nasal chambers and if there be any ocular manifestations of the disease, collyria composed of weak solutions of sulphate of copper or of sulphate of zinc may be employed. It is also recommended that the patient shall inhale ten drops of the iodide of ethyl from a handkerchief; or six drops of the nitrite of amyl will be found useful if employed at the beginning of the disease.

Ergotine in Gonorrhœa.—According to *La Médecine Moderne*, ROICKI, a Russian, uses the following solution of ergotine with extraordinary success in the rapid cure of gleet. The ergotine is administered in pill-form by the mouth and by urethral injections simultaneously. Injections are made up as follows:

℞.—Ergotine . . . . . 5 grains.
Distilled water . . . . 1 ounce.—M.

Use as an injection several times daily. It is stated that these injections are well borne and that the same treatment is applicable to hæmorrhages from either the ureters or urethra.

Incompatibility of Calomel and Antipyrine.—A writer in the *Western Druggist* points out the fact of the incompatibility of these bodies, a gray color developing in them when mixed and after moistening. The change is due to a reduction of the calomel and a simultaneous change in the antipyrine. The nature of the change has not been elucidated, but that the combination is a dangerous one, the writer indicates by calling to mind the fact that the death of a child has been reported in New York City, the fatal result taking place within a short time after the administration of a dose containing these two substances. The lists of incompatibles of antipyrine that have hitherto been presented have not included calomel.

Antipyretics.—A study of the action of the antipyretics has led DRS. PODANOWSKY and POPOFF to the following conclusions:

1. The antiphlogistic action of the quinine salts, resorcin and thallin, is due to their specific influence on the heat-centres in the anterior part of the cerebrum, for after the division of the spinal cord even very large quantities of those drugs do not change the cerebral temperature.

2. The nature of this action must be inhibitory, probably following a primary excitation.

3. The absence of influence by the majority of antipyretics upon the surface-temperature of animals whose cords have been cut, and hence with unchanged excitability of the vasomotor centres, corroborates the hypothesis of a special vasomotor centre in the anterior part of the brain, which probably serves for increased heat-dissipation in cases of excessive heat-production.—*Wiener med. Presse*, December 28, 1890.

Subcutaneous Injections of Creasote in Pulmonary Phthisis.—The following formula for the subcutaneous injection of creasote is proposed by CASSIN and TOUSSAINT:

℞.—Creasote . . . . 1 drachm.
Oil of sweet almonds . . ½ "

According to Cassin, the injection should be made into the tissues immediately below the scapula and deep enough to get into the loose cellular tissue.

Gimbert employs creasote two and a half drachms and olive oil five ounces, thoroughly sterilized. For the thorough sterilization of the oil it is sufficient to raise the temperature to 120° C. The injection should be made very slowly and the fingers should be placed over the orifice made by the needle when it is withdrawn, in order to prevent any of the liquid from escaping.

In from five to ten minutes the breath of the patient has the characteristic odor of creasote, and this odor persists for several hours. The injections may be practised every two days. The result of their use is a diminution in the expectoration, a return of the appetite, and a disappearance of night-sweats. Gimbert asserts that he obtains definite cures by this method of treatment.

The contra-indications to the employment of creasote are fever and hæmoptysis. It is thought that the value of its use depends upon pulmonary hyperæmia. Those patients who have the chronic form of phthisis and little fever, present the best opportunities for successful treatment.

The Proper Method of Using the Uterine Dilator.—Professor H. A. Kelly (*American Journal of Obstetrics*, January, 1891) reports the case of a young woman whose cervical canal had been dilated with Wilson's and Ellinger's instruments. When Dr. Kelly first saw the case, four days after the operation, she had symptoms of septic peritonitis and a fœtid discharge from the vagina. On examination a rotten, coarse sponge, the remains of a tent, was found projecting from the external os. On removing this, a rent about three-fourths of an inch long, half an inch above the os, and opening into the peritoneal cavity, was discovered. Abdominal section was advised, but was refused until five days later, when it was done with the patient almost moribund, death following in a few hours. It was evident that during the dilatation a small hole had been made by the small dilator and torn widely open by the large instrument, the sponge-tent being inserted into the rent and insuring infection of the peritoneum.

In commenting on this case, Dr. Kelly writes that the liability of perforating an anteflexed uterus by sharp and strongly-curved instruments is so obvious that the accident has probably occurred more than once. In inserting a dilator force should never be employed, but the instrument should be delicately poised between the thumb and first finger and gently "persuaded" to enter the canal, the direction of which should have been previously determined. Further, the method of dilating the canal by screwing together the handles of the instrument, with no relaxation, almost invariably causes a long laceration, sometimes through the entire thickness of the cervix. Instruments with ratchet and screw devices are, therefore, to be condemned, and one with a simple spring between the blades to be used. In operating with such an instrument Dr. Kelly carefully inserts the blades, gently dilates the canal for a moment in one direction, then relaxes the pressure, rotates the instrument slightly and again gently dilates, repeating the procedure until the canal has been twice gently dilated in every direction.

Treatment of Fissured Nipples.—According to the *Gazette de Gynécologie*, the following lotion is useful for the treatment of cracked nipples:

℞.—Balsam of Peru } of each ½ drachm.
Tincture of arnica }
Oil of sweet almonds . . 1 ounce.
Lime-water . . . . ½ "

Mix, and apply to the fissured nipple after the infant has finished sucking.

Injections for Gonorrhœa.—In the *Journal de Médecine de Paris*, Silberminz is said to use the following mixture for urethral injections in gonorrhœa:

℞.—Salicylate of mercury . . 3 grains.
Distilled water . . . . 4 drachms.
Gum arabic, a sufficient quantity to make an emulsion.

Shake well before using, and inject a small syringeful into the urethra three times a day.

The Use of Iodol.—According to Egasse, iodol presents great advantages over iodoform as an antiseptic. The author employs it in a solution made in the following manner:

℞.—Iodol . . . . . 1 part.
Alcohol (95 per cent.) . . 16 parts.
Glycerin . . . . . 34 " "

For inhalations, Cervesato employs the following:

℞.—Iodol . . . . . 1 part.
Absolute alcohol . . 4 to 5 parts.
Glycerin . . . . . 10 "
Water . . . . . 10 "

The iodol is dissolved in warm alcohol, and then added to a hot solution of concentrated glycerin, when a yellowish-brown color occurs in the solution.

Pick is said to employ iodol by dissolving one part in five of ether; or, where small abrasions are to be covered, he employs iodol collodion made in the following manner:

℞.—Iodol . . . . . 1 part.
Ether . . . . . 10 parts.
Gun cotton . . . . . 5 "

An ointment may also be made by adding 15 grains of iodol to 2½ drachms of vaseline, or from 5 to 10 parts of iodol to 100 of lanolin. Iodol-gauze may be prepared in the same manner as iodoform-gauze.

Treatment of Otitis Media Purulenta.—Pentkovski, a Russian, uses the following treatment for this condition. After distending the Eustachian tube with the Politzer air-bag, he washes out the ear with a warm solution of the sulphate of sodium, of the strength of five per cent., after which he uses the following mixture, heated to about the temperature of the body:

℞.—Essence of peppermint . . 3 grains.

Dissolve in absolute alcohol 75 minims, and add

Distilled water . . . . 1½ ounces.

Mix, and label "For external use."

After the external auditory canal has been cleansed by this application, he introduces a tampon of cotton prepared by immersing it in a solution of one-half to one per cent. of the essence of peppermint in sulphuric ether. After ten or fifteen days of this treatment the suppuration diminishes, and finally ceases. In other cases he employs a powder consisting of boric acid which contains one per cent. of the oil of peppermint.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: H. A. HARE, M.D,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 14, 1891.

PERTUSSIS AND ITS TREATMENT.

AMONG the diseases that have been proverbially obstinate in resisting our efforts to abort or shorten their course stands whooping-cough. The character of the disease is so complex, a mixture of catarrhal and neurotic phenomena, that authorities are still at variance in regard to its nature, and as to whether the catarrhal or the spasmodic element is the essential disease-phenomenon. That it has many features in common with diseases which are almost certainly of microbic origin has led to investigations that, unfortunately, cannot as yet be considered conclusive in regard to the presence of a specific germ. The curious nervous phenomena may at some future date be found entirely dependent upon the bronchitic condition, in which case the disease will resolve itself into an epidemic bronchitis. This view has been strongly urged and has been adopted by many, yet numerous careful observers still cling to the idea of a neurotic prime element.

The treatment of the disease has until lately been almost purely empirical, the two standard remedies formerly recommended for use as a routine practice being alum and belladonna. These drugs have their merits, but their field of usefulness has been more carefully defined in accordance with modern scientific therapeutics, while there are numerous remedies of later discovery that are fast gaining a foothold as either specifics or palliatives when properly used. A good *résumé* of the use of some of these remedies is given by DR. SICARD (*Revue de Thérapeutique Médico-Chirurgicale*, December 1, 1890), who briefly describes the methods of using and the virtues claimed for eight of the remedies whose employment is of recent date. His preference is evidently for antipyrine in frequently-repeated small doses. He denies that it acts both by its antiseptic and antispasmodic properties, and states that it is not a specific. In THE MEDICAL NEWS, December 13, 1890, DR. J. P. CROZER GRIFFITH publishes a paper confirming his former favorable report upon the use of antipyrine, and urges its employment in larger doses than those ordinarily used. Bromoform may be tried in cases in which the spasmodic element is marked and which antipyrine has failed to relieve, although it apparently possesses no advantages over the latter drug.

Among the older drugs employed for their antispasmodic action are belladonna and chloroform. The former of these, which has been used for so long a time with evident advantage against this and all other affections accompanied by spasm, cannot be omitted from the list of efficient remedies, while the place of chloroform may well be taken by its safer and equally-effective congener, bromoform.

In accordance with the view of the purely-reflex origin of the nervous phenomena of the disease many remedies for application to the throat and fauces have been highly recommended, but the exciting cause of the spasm, if it is in reality merely reflex, is probably seated too far down in the respiratory tract for such remedies to reach. Other remedies for topical application have been recommended on account of their anti-microbic action. Of these, resorcin and carbolic acid have been the most generally adopted. With a similar object the continuous inhalation of the fumes of sulphurous acid has been much practised, and possesses the great advantage that the method can be combined with the employment of other remedies, the patient merely sleeping in an apartment which has been subjected to the action of burning sulphur.

Against the catarrhal element we have lately acquired a valuable drug in terpine hydrate, which in the hands of some has given excellent results. This drug, or some of the older and more generally used expectorants, may be employed in selected cases with the addition of alum, the salts of zinc, or nitric acid, if the catarrhal products are in excess.

With such an array of antiseptics, antispasmodics, and expectorants we would seem to need nothing but a specific to complete our armamentarium. Although many of the remedies mentioned have been vaunted as specifics by their most ardent advocates, it is probable that before any such remedy is found we must have more exact knowledge of the true nature of the disease. In Dr. Sicard's article results are mentioned which are truly wonderful in their promptness as recorded by the originators or advocates of the various drugs. That others have been unable to obtain similar results in such a universally-similar disease as pertussis can be attributed either to imperfect observation by the successful or to a faulty carrying-out of the methods by the non-successful reporters. In all likelihood the latter is more frequently the cause of failure, and it should be constantly borne in mind that it is more harmful to make an unfavorable report upon a remedy that has not been *properly* used than to remain inactive in the field of therapeutic research. Probably, as Dr. Griffith remarks in the article referred to, failure to use the remedy in sufficientl-ylarge doses has been the cause of much of the disappointment to those who have been unable to obtain good results from antipyrine in this disease. That none of the drugs so far brought forward are specifics is probably true, but when properly used some of them have a marvellous power to control the spasmodic element, and thereby, indirectly, the vomiting and hæmorrhages that frequently cause an otherwise simple case to assume a dangerous character.

OBSTETRICAL ANTISEPSIS.

The features of obstetrical teaching that will make the strongest impression on the present era of obstetrical progress are the proper use of antiseptic precautions, and the results for good which have been brought about by a wise application of this principle. From the early work of Semmelweiss—that now represents the true foundation of all the progress that has since been realized in this direction—until the present time, there has been a continual effort made in all parts of the world to improve the results obtained in maternity hospitals, not only in the death-rate, but also in the febrile complications following labor. When epidemics of puerperal fever were common, and the death-rate in lying-in hospitals was truly murderous, that great obstetrician, Semmelweiss, was the first to realize that the trouble arose from the absorption of putrescent animal substances which had been deposited in or about the genital tract of the parturient woman. The precautions he took to combat the terrible death-rate (9.92 per cent.) of the Vienna Obstetrical Clinic were simply those of forbidding the attending physicians to perform autopsies, and requiring everyone who handled the patients to disinfect their hands previously with chloride of lime. Immediately after the institution of those precautions the mortality in his wards fell to 1.27 per cent.

For years the deductions of this much-underrated obstetrician were neglected and scoffed at. However, since the experiments of Pasteur and Lister have been widely studied, the principle of antiseptic cleanliness has been generally accepted and applied to all obstetrical procedures, and, in proportion as this principle has been carefully carried out, the results in different maternities have been improved.

In the *Transactions of the Obstetrical Society of London*, June and July, 1890, Robert Boxall, M.D., contributes an elaborate article on the subject of antiseptic precautions as carried out in the General Lying-in Hospital of London during the last seven years. For several years prior to this time, the hospital was closed on account of the terrible mortality which had attended its service. When the wards were re-opened in 1882, it was under a strict antiseptic *régime*. From July 1, 1882, to April 30, 1884, there were 612 admissions, and the death-rate was only 0.980 per cent. From May 1, 1884, to June 30, 1889, there were 2150 admissions, and, under an increased improvement in the details of treatment, the death-rate fell to 0.418 per cent. During the first period (more than a year and a half) the labors followed by fever from all causes amounted to 83.006 per cent.; during the second period, or until 1889, this was reduced to 40.651 per cent. This rapid improvement is a repetition of the experience of all modernized maternity hospitals. However, there is yet room for great improvement. A death-rate of 0.418 per cent. is about as small as any maternity may expect to attain, but fever following 40.651 per cent. of labors is enormous, and can be readily reduced. In this hospital apparently the same mistake is made that is so often made elsewhere. There seems to be a tendency to adopt the common idea, that if there is good in a little of any given remedy, there must be more good in a great deal of it. When patients are admitted to the hospital "they are immediately dressed in hospital

clothes, and, in all cases in which time will allow, the passages are irrigated with three quarts of antiseptic solution before delivery, the douches being repeated if the labor be prolonged. One or more such vaginal douches at a temperature of 115° F. are invariably given after labor is completed. The vaginal douche at a temperature of 110° F. is employed as a routine measure, night and morning, until the lochia have ceased." Is it not possible to account for at least a part of this large percentage of febrile complications by the too free use of mercurial douches? In Pesth, in a series of cases in which no injections whatever were used, 82.78 per cent. of the patients remained free from fever. In another series of 300 cases in Germany there were 94 per cent. with no fever. In Berlin, in a series of 422 cases, 90 per cent. remained free from fever. In Dresden, Leopold gives the following comparison: Of 1388 deliveries with injections, 17.2 per cent. had fever; of 1136 deliveries with injections and vaginal washings, 20 per cent. had fever; of 1123 deliveries with no injection at all, only 9.7 per cent. had fever. The antiseptic precautions in all these cases were applied to everything which approached the woman, but not to the parturient tract. It was assumed that the infection came from without, and not from within; and the results certainly warrant the conclusion. It would seem, from this, that we are still about where Semmelweiss left us.

The surgeons of the General Lying-in Hospital have found that, as in general surgery, the mercurial salts are the most efficient of the antiseptics. An extended trial of salufer, permanganate of potassium, and carbolic acid was made, but in every instance the mortality- and fever-rate exceeded that which occurred when the salts of mercury were used. From the fact that creolin has not been used in this hospital, it is to be presumed that there was a lack of confidence in its efficiency.

The good results attained in this hospital are further evidence that obstetrical cases can be safely used for teaching purposes. Although students are not admitted to the wards, yet there is a flourishing school of both nurses and midwives attached to the institution.

THE DIAGNOSTIC VALUE OF THE FIBRINOUS ELEMENTS OF THE BLOOD.

It is a well-established fact that, secondarily at least, the blood partakes in tissue-changes, and becomes more or less altered in constitution. There are strong reasons for supposing that the participations of this fluid in the phenomena of inflammation are not simply those of solution which are generally accepted, but that in such a condition it presents alterations in constitution not only in consequence of its assumption of the products of the cellular changes, but also to aid in the fulfilment of the inflammatory process. These changes are not so much alterations of the red corpuscles, as those variations in the fluid-elements by which the possibility of forming fibrin is increased. With this there probably coëxists numerical alteration in the leucocytes, or anomalies in their size. Such alterations are evidenced, of course, by the greater tendency of the blood to coagulate, and are present in order to bring about in the inflamed area a skeletal formation of fibrin upon which the regenerative changes shall occur. In the days of venesection such a condition, partly described under the term *hyperinosis*, was recognized; but with the gradual disuse of this procedure as a therapeutic measure, the hæmic fault was also allowed to fall into neglect. The microscopists are not entirely inculpable in this neglect of an important feature, since, in this country at least, with the possible exception of a few practitioners of questionable standing, practically no attention is paid to this matter; although there is little doubt that there exist certain quite perceptible differences in the manner of formation and the mode of arrangement of the fibrin in the clotting of blood in a number of different diseases.

According to Hayem, in his classic treatise upon the blood (*Du sang et ses alterations anatomiques*, par Georges Hayem, 1889), Masson recognizes three types of coagula: (1) that in which there exists a very intricate network of rather coarse fibrils with numerous and large accumulations of plaques; (2) that in which the coarse fibrils are present but fail to form so intricate a network, and in which the plaque-masses are not so marked; (3) that in which the network of fibrin is delicate and composed of very fine fibrils, remarkable also for their great numbers. The first of these types is referred by Hayem to such processes as the early stages of fibrinous pneumonia, acute rheumatism, the suppurative inflammations, etc.; the second to the beginning of inflammations of a somewhat diffuse character, and to secondary or symptomatic inflammations; the third to parenchymatous inflammation especially, and in some cases to symptomatic inflammation.

Following in this line, Oriou (*Archives de Méde-*

cine et de Pharmacie Militaires, October, 1890) claims diagnostic value for the microscopical examination of the fibrinous reticulum of the clot in the following conditions: *la grippe*, acute gastritis, and typhoid fever; pulmonary, pleural, laryngeal, and abdominal tuberculosis, and tuberculosis of the bones and joints; muscular and acute articular rheumatism, acute bronchitis, acute pneumonia; and in localized and diffuse suppurations. In the case of *la grippe*, Oriou states that this fibrinous reticulum becomes apparent in the early days of the affection; that as a rule it assumes the third type of Hayem, although in certain complications it changes to the second; and that it disappears with the disappearance of the fever unless there persist in the febrile state any visceral inflammatory conditions as gastro-intestinal catarrh or bronchitis. The character of the fibrinous reticulum in the blood taken from a case of gastro-intestinal inflammation, as from any other simple inflammation, largely depends upon the intensity of the inflammation, and the value of the phenomenon in these cases is particularly in the separation of a simple process from one of specific character, such as typhoid fever. In the latter disease the blood usually fails to present any fibrinous reticulum for the first seven or eight days and, as a rule, at no stage shows more than an imperfect reticulation.

Generally speaking, the same is true of tuberculosis and other specific processes. In these conditions there is no reticulation save in the presence of pronounced inflammatory complications, the specific process having no tendency to produce the phenomenon.

Of especial value from these considerations must be the determination of the presence or absence, and the character, if present, of the fibrinous reticulum in cases in which the nature of a disease-process located in the gastro-intestinal tract, in the pulmonary system, or in any other portion of the body, is questioned. For example, acute croupous pneumonia presents the most pronounced type of reticulation, of exceeding intricacy and composed of large heavy fibrillæ; a *grippal* pneumonia is apt to present a slight reticulation, one of the delicate forms, corresponding, as a rule, to type three of Hayem; typhoid pneumonia rarely presents reticulation at any period of the process; tubercular pneumonia should show but imperfect reticulation, if any, unless it be accompanied by considerable inflammatory reaction; rheumatism usually presents a marked reticulum in the clot of the first type of Hayem, and is readily separated from other localized painful affections by this peculiarity.

In the nature of things, the existence of such differences in the physiology of the most generally present tissue of the body is probable, and it is remarkable that so little attention has been paid to a subject of such importance. The technique of the examination is not especially complicated or tedious, and the apparatus required is simple. A drop of blood is placed upon a slide and the slide transferred to a moist chamber until coagulation has taken place, a cover-glass having been, of course, placed over the blood. The slide is then removed from the chamber and a delicate process of lavage carried out by dropping on one side of the cover a small quantity of distilled water so that it penetrates the reticulum, and drawing it through the mass by a bit of absorbent paper held in contact with the edge of the cover on the other side. By this means the red and white cells and plaques are removed from the reticulum, bringing it into prominence and permitting study of its characteristics. In this process of lavage a slide carefully and evenly grooved aids in the rapidity of the procedure and prevents in a great degree any damage to the reticulum. After the mass has been thus washed a drop of dye, such as rosaniline hydrochlorate, is substituted for the water and drawn through the mass in the same manner; the excess of dye is washed out with water and the preparation is ready for examination.

There is little to be said in comment. The possibilities in diagnosis are limited, but of such importance in their limitation that the general hesitation at even a tentative employment of the suggestion is inexplicable.

REVIEWS.

EINFUHRUNG IN DAS STUDIUM DER BACTERIOLOGIE. Von Dr. med. CARL GUNTHER, in Berlin. Pp. 244. Leipzig: George Thieme, 1890.

IN 1863, in Delft, Holland, the first recorded observation and recognition of bacteria took place, the observer, Leeuwenhoek, calling attention to his discovery of "animalcules" in the material which collects about the teeth and in various fluids of the body. The organisms were seen by means of a powerful simple lens, which he himself had ground. Since this date, the bulk of the work having been accomplished within the last thirty years, and chiefly in the past decade, our knowledge of these vegetable micröorganisms has grown from a few isolated facts into a science influencing every branch of medicine. Following the development of this science there has grown a vast literature; and the number of

bacteriological text-books is constantly increasing. Few of these are without reason for existence, the rapid strides of our knowledge in this field necessitating the multiplication of books. Of these books, however, few are destined to live beyond the first edition; and still fewer run any serious risks of ever becoming regarded as classics.

While the work of Dr. Gunther's is in no danger of this last possibility, it is far above the average of the numerous technical and descriptive bacteriological works. It is divided into three sections, the first treating of the general methods of bacterial technology, the second dealing descriptively with the pathogenic varieties, and the third with the non-pathogenic forms. Throughout the text there is to be noted an excellent feature in the recognition of the historical details of the various bacteria and methods, a feature almost invariably wanting in other works upon this subject. The references in the text are numerous and notably up to date, but it must be added that they are also notable because of their close adherence to German authorities. This same feature is quite as well marked in the recognition of the precedence for German investigators over those of other nations. These objectionable peculiarities, for such a characterization seems warrantable, may be pardoned, however, in view of the unquestioned success of the German nation as scientific investigators.

What may cause disappointment in this work to those who seek a bacteriologist's *vade mecum* is, that the writer has not recognized many of the media and methods employed in staining and culture, usually mentioning but a few of the well-tried ones. These are, however, fully and clearly presented. While this may be regarded as an excellence in the general portion of the book, in the descriptive portion (where every element should be mentioned as a possible factor in isolation) it must be looked upon as a serious omission. For example, the description of so important a microörganism as Eberth's bacillus of typhoid fever has received scarcely more than a brief paragraph, although two or more pages of text are devoted to the consideration of its history and the experimental researches touching upon its influence in the production of disease. In this case no ideas of mensuration are given. The same criticism may be made regarding other germs, especially those of the non-pathogenic varieties.

In relation to the many excellent features of the book as an introduction to bacteriology, these faults do not have by any means the prominence which might seem to attach to them. The clearness of presentation, the fulness of the historical and experimental considerations, the simplicity of plan, and the excellent photomicrographic plates, are sufficient to prevent the book from being seriously marred by the faults mentioned.

CORRESPONDENCE.

LONDON.

Mr. Jonathan Hutchinson on the Relationship of Lupus to Tuberculosis.

A few days ago Mr. Jonathan Hutchinson delivered an important lecture on "The Nature of Lupus, with especial Reference to its Relation to Tuberculosis," at the examination hall of the College of Physicians and Surgeons. It is, I believe, the first time that such a use has been made of the building, and the occasion was the commencement of the second London post-graduate course, in which, from its beginning, Mr. Hutchinson has taken great interest. The audience, which numbered about one hundred persons, included Sir Joseph Lister and Sir Andrew Clarke.

At the commencement of the lecture Mr. Hutchinson demonstrated the prominent features of the disease, as exemplified in a young woman whom he brought before his hearers, and pointed out how the disease tended to attack the areas especially concerned in flushing or blushing, and those much exposed, for example, the cheeks and tip of the nose. Premising that he approached his subject solely from a clinical point of view, he said that the first thing to consider was whether the typical form of lupus vulgaris is always of bacillary origin. There are two possibilities to be borne in mind: first, the lupus-process may be always due to the implantation of the parasite bacillus in the tissues, or second, the process may originate as a variety of inflammation, induced by any one of many local causes of irritation and nutritional change. He at once expressed his own leaning to the view that it is highly improbable that true lupus is always the result of contagion, and that it usually begins in inflammatory action made peculiar by the special proclivities of the individual. In his opinion, lupus is not always a well-defined and easily-recognizable disease, and no symptom or set of symptoms will enable one to recognize with certainty all cases of lupus, and to determine what should and what should not be included under that name. His definition of the lupus-process was given in the following words: "Whenever a chronic inflammation of skin or of mucous membrane, not due to syphilis, shows a persistent tendency to spread at its edges, to produce satellites near it, and to leave a condition of scar behind it, such a process is for me one of lupus. In a few cases the production of satellites may be omitted and the patch may remain absolutely single, but its infective edges and the resultant scar are essential. No form of lupus is without them, although it must be admitted, perhaps, that in a few the demonstration of the scar may be difficult. There is another condition which when present is to trained minds definitely diagnostic of lupus. I refer to the presence beneath a thinned layer of epidermis of a deposit or growth of semi-translucent granulation-material, often in considerable thickness. This 'apple-jelly-like' deposit, as it has been named, is, when present, perfectly characteristic of common lupus." Amongst minor features of the lupus-process he mentioned that if the surface does not ulcerate it is usually covered with white papery flakes of epidermis which, however, do not fall off; if the patch is ulcerated a dried crust forms, which, when removed, leaves a bleeding surface.

Lupus vulgaris is most common on the tip of the nose, the next most frequent seat being the cheek. It is not uncommon on the limbs but very rare on the trunk. The patches are never symmetrical. Though occasionally seen in children, it does not often develop until after the period of puberty. The lymphatic glands, lungs, bones, joints, and intestines, are never affected.

Nothing is less common than to see a lupus-patient develop phthisis. The most typical forms are often coincident with good general health, and with the absence of any family history of tuberculosis. He believes that lupus is as closely related to cancer as to tuberculosis, and that an unbiased statistical investigation would show that the latter association is not so frequent as is commonly assumed.

Reminding his hearers that syphilitic symptoms could imitate lupus, he said that since syphilis in its tertiary stage is only a chronic infective inflammation, deriving its peculiarities from the antecedents of the patient, and having nothing whatever to do with tuberculosis or bacilli, it is reasonable to suppose that lupus, which so exactly resembles it, might also be a process of chronic inflammation made peculiar by the vital proclivities of the patient. If lupus were of bacillary origin he thought it remarkable that in gland struma the skin does not assume a lupus-state and that the glands never become involved in lupus. Of primary tubercular ulceration of the skin he has had no personal experience but tubercular ulceration of mucous membranes presents characters quite distinct from those of lupus in that situation.

In conclusion he said, "I may own that the sum of the evidence seems to me much in favor of the belief that lupus is a specialized form of chronic inflammation rather than the result of infection. In suggesting this I am well aware that it is merely a negative conclusion, which is liable to be overthrown at any time by the accumulation of positive evidence. It may be that in the future the presence of bacilli in lupus-products may be demonstrated in earlier stages, and much more constantly than has yet been the case. The results of Koch's injection-treatment may possibly force us to believe that there is something about lupus which connects it far more closely with tuberculosis than I have admitted."

ABSTRACTS FROM "THE PICTURE OF PHILADELPHIA," ETC.[1]

IN an extremely interesting historical and statistical account of the city of Philadelphia, published in 1811,[2] with the keen eye and tastes of a physician, Dr. Mease has recorded many facts of deep interest to the medical historian. The few following extracts from this book, although loosely strung together, present an excellent picture of medicine in Philadelphia in the first decade of this century:

Philadelphia at that time consisted of nine original streets running east and west from the Delaware to the Schuylkill, and thirteen streets crossing these at right angles. The streets running east and west were named, with the exception of High (Market) street, for the native trees: Vine, Sassafras (Race), Mulberry (Arch), High (Market), Chestnut, Walnut, Spruce, Pine, and Cedar (South). The territory immediately outside these boundaries was called the "Liberties," as the people there were out of the city jurisdiction.

The population in 1810 was 53,722,[1] of whom 2 were slaves. Dr. Mease attributes the great increase in population over that of 1790 (28,522, of whom 193 were slaves), in spite of five epidemics of yellow fever, to the number of marriages and the inducements to immigration, and to a general improvement of the public health, due in part to the successful efforts of Dr. Rush in inducing the Legislature to arch over the Dock-street creek, which had become filled with mud, unfit for navigation, and a receptacle of an immense mass of animal and vegetable offal matters which poisoned the air by their exhalations. After this creek was thus covered in, he remarks that typhus fevers generally, and the fatal cholera, or bowel complaints of little children, diminished so evidently as to strike even common observers. Improvement was also due to "greater attention to cleanliness, to the institution of a dispensary for the poor, and to improvements in the healing art."

He remarks of the climate that a considerable change had taken place, the winters being less uniformly cold, the Delaware for many years past not affording the diversion of skating for more than two weeks at a time, and seldom so long. In the winter of 1779–80 it was frozen for three months, and an ox was roasted on the ice. The rain, in most parts of the United States, he says, falls in greater torrents than in Europe, and we know but little of those "fine, gentle showers" which, Volney says, "it is the fashion for people to go out to enjoy without umbrellas, and to get themselves wet to the skin!"

We read that "the death-rate is diminished by the very great improvements in the science of medicine and surgery. Many diseases now yield to the power of the healing art that formerly defied it. Thirty years since, the disease from drinking cold water in summer when the body was heated with exercise, the lockjaw, the croup or hives, mania, were seldom or never cured; but, at present, they are very rarely fatal when early assistance is given. The first-named disease is peculiar to the United States, and with regard to the last two it is asserted on good authority that the success in Philadelphia is infinitely greater than in Europe. Even the consumption, formerly a hopeless disease, has yielded, in numerous cases in this city, to the early and judicious application of medicine. The free use of wine in low fevers, of mercury, bark, opium, and the lancet, and warm and cold baths, has increased the empire of medicine over various diseases."

He further states that the character of our diseases is inflammatory, owing to the variable climate, and the general use of animal food and alcoholic stimulants. Hence the lancet is oftener required than the stimulating draught —to the astonishment of the European physician hearing of the depleting system of the United States and especially of Philadelphia.

An improvement, however, was taking place, due, among other things, in the author's estimation, to the substitution of malt liquors for punch, and to the use of flannel or muslin next to the body expelling the "dry gripes," formerly a fatal disease in Philadelphia. Important, also, says he, is the universal use of umbrellas,

---

[1] Read before the Historical Society of the Johns Hopkins Hospital, by Howard A. Kelly, M.D.

[2] By James Mease, M.D. Philadelphia, B. & T. Kite, 1811, pp. 376.

[1] The whole population of the city and county of Philadelphia in 1810 was 111,210, while that of New York, embracing the entire island, was 96,372.

and the increased use of high-crowned hats, lessening diseases arising from the operation of the sun.

The mortality record in 1811 was made up by compelling the sextons of all churches to make returns of their burials. After stating the mortality, he says: "If the population of Philadelphia, as being greater than that of New York, be taken into consideration, the difference in favor of Philadelphia will be considerably increased." We read that the air of New York was more irritating, and persons who had spat blood in New York were entirely free from any pulmonic affection in Philadelphia.

There is an interesting account of the foundation of the Pennsylvania Hospital, first located on Market Street, west of Fifth. There were in this building, in all, 130 wards and rooms, of which 86 were apportioned to the lunatics and 23 to the sick and wounded. The lunatics being separated from the sick by the centre house, the latter were not incommoded by their noise. The library then contained 3000 volumes of choice medical books.

An amputation of a limb was not to be performed in the hospital unless a patient consented to it, nor then unless three physicians agreed.

"The present [in 1811] physicians are Dr. Rush, Dr. Parke, Dr. Wistar, Dr. Physick, Dr. Barton, Dr. Hartshorne, and the physician to the lying-in department, Dr. Thomas C. James."

In speaking of the University of Pennsylvania, he says: "In the year 1764 the foundation of the first medical school in America was laid by a course of lectures upon anatomy, which was delivered by the late Dr. William Shippen. His pupils amounted to ten. He was appointed professor of that branch, in the following year, by the trustees, and Dr. John Morgan, professor of the institutes of medicine. Both these gentlemen had graduated at Edinburgh, and had previously agreed to attempt the establishment of a medical school on their return. In 1768 Dr. A. Kuhn was appointed professor of botany, and in 1769 Dr. B. Rush was appointed to the chemical chair; Dr. T. Bond at the same time gave clinical lectures in the Pennsylvania Hospital. After bitter internal dissensions, in 1791 the seminary was erected now called the University of Pennsylvania, with the addition of chairs of natural history, law, and the German language."

The professors in the medical school were: Caspar Wistar, Jr., M.D., Professor of Anatomy; Benjamin Rush, M.D., Institutes and Practice of Physic and Clinical Practice; Philip Syng Physick, M.D., Professor of Surgery; John Syng Dorsey, Adjunct Professor of Surgery; Dr. Benjamin Smith Barton, Professor of Materia Medica, Botany, and Natural History; T. C. James, M.D., Professor of Midwifery; and John Redman Coxe, M.D., Professor of Chemistry.

For the loan of this interesting work I am indebted to my friend Dr. W. H. H. Githens.

NEWS ITEMS.

Lister's Work.—Lister's work since he took his first degree in 1852, has been of a character to command the respect and admiration of the scientific world. Receiving the first prizes in botany and anatomy when he passed the M. B. examination, he won the gold medal and the scholarship in surgery in the final examination. His papers on the minute anatomy of the skin, the physiology of the lacteal current, the contractility of the iris, the microscopic anatomy of involuntary muscular fibre, the relations of the inhibitory system to the visceral nerves, the regulation of arterial contraction by the nervous system, the early stages of inflammation, the coagulation of the blood, etc., stamped him at once as an original investigator of the first rank, and, as one of his biographers says, "would have sufficed to make his career memorable if he had never applied antiseptic measures to the treatment of disease." I have heard Professor Louis Agassiz years ago and later Professor Joseph Leidy say that, viewed from the standpoint of abstract science, his work had been of the very highest order and the appreciation of his labors by the best minds in our own profession has been enthusiastic and almost universal. Nearly every great surgeon in the civilized world has put on record his admiration for Lister's teachings, his acceptance of the general principles involved and his sense of almost personal obligation to the author of the antiseptic theory.

That Mr. Tait should speak of such a man as having "lived in the clouds of his spray for the last twelve years," as "wanting in logic," having "crude notions of logical definition," making "illogical blunders," "falling away from his own faith," promulgating an "absolute and ludicrous logical error," etc., and should make a boast of having "laughed at" and "ridiculed" him and his doctrines and disciples, is, it seems to me, evidence of his unfitness by temperament or training (or from lack of the latter) for the serious discussion of broad surgical principles. I am quite sure that the vast majority of general surgeons will be found to have no sympathy with either his views or his manner of expressing them, and it is a relief to find that in his own special line there are operators of equal eminence who repudiate both. In an address on "Abdominal Surgery, Past and Present," recently delivered before the Medical Society of London, its president, Mr. J. Knowsley Thornton, said: "I am not ashamed still to use the spray and all the precautions which have advanced my results in ovariotomy to 1.88 per cent. mortality (as against Bantock's 4 and Tait's 3.3 per cent.), and I find increased practice and a steady adherence to methods which have yielded me good results in the past increase in like ratio my success in all abdominal operations. Every operator of prominence improved his results enormously as soon as he adopted Listerism; then, having learned how to be surgically clean, he has found for himself ways of attaining this end with more or less success by methods differing from those of Lister. The sum and substance of it all is, that if we never had Lister to teach us true cleanliness, we should never have used antiseptics, flushings or drainage-tubes to attain it." —Dr. J. William White, in the *Annals of Surgery*, January, 1891.

Dr. Norman Bridge, Professor of Clinical Medicine and Physical Diagnosis in Rush Medical College, Chicago, has been compelled by ill-health temporarily to abandon his professorship and practice. He has gone to Los Angeles, California.

Compulsory Vaccination in Egypt.—By a Khedival decree which was published in the *Official Journal* of

Cairo on December 17, 1890, the vaccination of infants is made obligatory throughout Egypt and its dependencies Every child is to be vaccinated within three months from its birth, except in case of illness, when a medical certificate of postponement is to be obtained. Arrangements are made for the gratuitous performance of the operation, and the duty of securing the vaccination is imposed on the child's father or guardian under pain of a fine or imprisonment. The decree went into operation on its publication December 17th as regards natives, but three months' grace is allowed to foreigners. —*British Medical Journal*, January 3, 1891.

New Jersey State Medical Examination.—The following were the questions of the Medical Examining Board of New Jersey at the meeting of January 8 and 9, 1891:

SECTION I. *Materia Medica and Therapeutics.*
(William L. Newell, M.D., Examiner.)

1. What medicines are incompatible with cinchona?
2. What preparations of quinine are best adapted to subcutaneous use?
3. Give a test for iodide of potassium?
4. What is chloroform? What are its physiological effects?
5. What is the treatment for an overdose of aconite?
6. What are the vegetable acids?
7. What are the physiological effects of the salts of lead?
8 What are the physiological effects of mercury and its salts?
9. Write a prescription containing a salt of lithia, and give the pathological condition intended to be relieved.
10. What are the officinal preparations (and dose of each) of opium and its alkaloids?

SECTION I *A. Homœopathic Materia Medica and Therapeutics.* (A. M. Worthington, M.D., Examiner.)

1. Explain methods of preparing medicines by attenuation, solution and trituration, by the decimal system.
2. Give a brief botanical description of gelsemium sempervirens.
3. What are the laryngeal symptoms of hepar sulphuris?
4. Name the remedies of greatest value in acute articular rheumatism.
5. What are the lung symptoms of phosphorus?
6. Give the heart symptoms of convallaria majalis.
7. Name the indicated remedies for parenchymatous tonsillitis—primary and suppurative stages.
8. Describe the characteristic diarrhœa of croton tiglium.
9. Differentiate the skin symptoms of thuja occidentalis and graphites.
10. Give the abdominal symptoms of veratrum viride.

SECTION II. *Obstetrics and Gynecology.*
(Dr. Brown, Examiner.)

1. What is natural labor?
2. How many stages in a natural labor, and how are they divided?
3. Give the treatment of the third stage of a natural labor.
4. What are the functions of the placenta?
5. Give indications for and methods of inducing premature labor.
6. Give the treatment of abortion.
7. What are the differences between the male and female pelvis?
8. Give the symptoms and treatment of puerperal eclampsia.
9. Give the symptoms and treatment of uterine polypi.
10. Give the causes, symptoms, and treatment of rupture of the perineum.

SECTION IV. *Physiology.*
(D. R. Atwell, M.D., Examiner.)

1. What is a proximate principle? Give classification of the same.
2. What are the functions of the retina and iris?
3. What is the function of the placenta?
4. Give the normal surface-temperature of the body, and name influences which produce variation from the normal.
5. What forces keep the blood in circulation?
6. For what do the lacteals and mesenteric veins serve?
7. Give the percentage composition of human milk.
8. For what does the skin serve?
9. Give the physiological properties of the pneumogastric nerve. Over what organs does it preside?
10. Describe the excretory process of the kidneys.

SECTION V. *Anatomy.*
(A. Uebelacker, M.D., Examiner.)

1. Describe the humerus.
2. Describe the shoulder-joint.
3. Enumerate the muscles of the acromial, anterior and posterior scapular regions.
4. Describe the patella and muscles attached to it.
5. Give origin, course, and divisions of right carotid artery.
6. Describe the external jugular vein.
7. Describe the vertebral artery.
8. Describe the radial artery.
9. Describe the ophthalmic nerve.
10. Describe the tongue.

SECTION VI. *Surgery.*
(Hugh C. Hendry, M.D., Examiner.)

1. State the recognized fractures and dislocations of the head of the humerus, and give the differential diagnosis of each.
2. Give symptoms, diagnosis, and treatment of backward dislocation of the elbow.
3. State the recognized fractures of the head of the femur, and give the differential diagnosis.
4. Give the immediate symptoms and remote effects of a severe concussion of the spine in the lumbar region.
5. Treatment of wounds: Describe the antiseptic methods as at present employed. Give the names of several antiseptics and the manner of using them.

SECTION VII. *Chemistry.*
(Eugene Tiesler, M.D., Examiner.)

1. Give three tests for sugar in urine.
2. What is the difference between slacked and quick lime?

3. Give tests for arsenic in solution.

4. By what methods are volatile oils obtained, and how do they differ from fixed oils?

5. What is alcohol? How is it produced?

6. In what form is mercury present in the unguent. hydrarg. ciner.

7. Define bismuth subnitrate. How is it prepared? Give properties.

8. What is spirit mindereri? How do you prepare it?

9. What is oil of vitriol?

SECTION VIII. *Histology, Pathology, and Diseases of the Eye and Ear.* (H. G. Wagoner, M.D., Examiner.)

1. Describe muscular tissue.

2. Describe nerve tissue.

3. Give the lesions characteristic of typhoid fever.

4. Give the pathology of arsenical poisoning.

5. Give pathology of acute, chronic, and tubercular meningitis.

6. Give the pathology of lupus.

7. Describe hypertrophy of the heart, without and with dilatation.

8. Give symptoms and treatment of furuncle of the external auditory canal.

9. Give causes, symptoms, and treatment of purulent ophthalmia.

10. Explain exophthalmic goitre, symptoms and causes.

SECTION IX, *Hygiene and Medical Jurisprudence.* (A. H. Worthington, M.D., Examiner.)

1. Name the diseases that may be caused by drinking impure water.

2. What method would you advise to destroy the disease-producing germs that impure drinking-water may contain?

3. What is the normal quantity of carbon dioxide in the atmosphere, and what proportion in the air is sufficient to cause sudden asphyxia?

4. What is the difference between an antiseptic, a deodorant, and a disinfectant?

5. Names the acids, acetic, boric, carbolic, and salicylic, in the order of their strength as germicides.

6. What are the ordinary signs of death?

7. How soon after death is the best time to make a post-mortem examination for medico-legal inquiry?

8. How would you distinguish an ante-mortem bruise from a post-mortem ecchymosis?

9. State the chief distinctive marks to determine the sex and probable age of a human skeleton.

10. How would you diagnose alcoholic coma from apoplexy, or an injury to the brain?

Arsenic in Commercial Acids.—BUCHNER calls attention to the fact that commercial hydrochloric and sulphuric acids contain large quantities of arsenic. On examination in 200 pounds of sulphuric acid were found 4 ounces of arsenious acid and nearly four times as much arsenic was found in a sample of hydrochloric acid.—*American Journal of Pharmacy*, February, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 3 TO FEBRUARY 9, 1891.

By direction of the Secretary of War, JAMES G. MERRILL, *Captain and Assistant Surgeon*, is relieved from duty at Fort Reno, Oklahoma Territory, and will report in person, at the earliest practicable date, to the Surgeon-General of the Army, in this city, for duty in his office.—Par. 5, *S. O. 29, A. G. O., Washington. D. C.*, February 5, 1891.

DAVIS, WILLIAM B., *Captain and Assistant Surgeon.*—The leave of absence for seven days granted, by Orders No. 2, Fort Preble, Maine, February 4, 1891, is hereby extended twenty-three days, with permission to apply to the Adjutant-General of the Army for a further extension of one month.—Par. 2, *S. O. 22, Headquarters Division of the Atlantic, Governor's Island, New York*, February 5, 1891.

CHAPIN, ALONZO R., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, with permission to apply to the Adjutant-General of the Army for an extension of one month, Fort Yates, North Dakota.—Par. 3, *S. O. 17, Department of Dakota, St. Paul, Minnesoto*, January 31, 1891.

By direction of the Secretary of War, CALVIN DE WITT, *Major and Surgeon*, is relieved from duty at Fort Hancock, Texas, and will report in person to the commanding officer, Fort Sam Houston, Texas, for duty at that station.—Par. 1, *S. O. 27, A. G. O., Washington, D. C.*, February 3, 1891.

By direction of the Secretary of War, WILLIAM STEPHENSON, *Captain and Assistant Surgeon*, will proceed, without delay, from Columbus Barracks, Ohio, to Fort Wayne, Michigan, and report in person to the commanding officer of that post for temporary duty, and upon completion thereof will return to his proper station—Par. 13, *S. O. 23, A. G. O., Washington, D. C.*, January 28, 1891

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FIVE WEEKS ENDING FEBRUARY 7, 1891.

BAILHACHE, P. H., *Surgeon.*—Granted leave of absence for seven days, January 12, 1891.

PURVIANCE, GEORGE, *Surgeon.*—To proceed to Pittsburg and Erie, Pa.; Cleveland and Toledo, Ohio; Detroit, Mich.; and Buffalo, N. Y., as inspector, December 29, 1890.

CARRINGTON, P. M., *Passed Assistant Surgeon.*—Granted leave of absence for seven days, January 16, 1891.

GEDDINGS, H. P., *Assistant Surgeon.*—To report in person to the Supervising Surgeon-General, January 16, 1891. Detailed for special duty, port of Georgetown, D. C., January 19, 1891.

STURGEON, W. G., *Assistant Surgeon.*—To proceed to New Orleans, La., for temporary duty, January 6, 1891.

SAWTELLE, H. W., *Surgeon.*—Detailed as a member of the Board, Revenue-Marine Service, January 26, 1891.

AUSTIN, H. W., *Surgeon.*—Detailed as Chairman of Board for Physical Examination of Officers of Revenue-Marine Service, January 28 and February 6, 1891.

PETTUS, W. A., *Passed Assistant Surgeon.*—Detailed as Medical Inspector of Immigrants, Port of Boston, Mass., January 29, 1891.

MAGRUDER, G. M, *Passed Assistant Surgeon.*—Detailed as Recorder of Board for Physical Examination of Officers of Revenue-Marine Service, January 28 and February 6, 1891.

KINYOUN, J. J., *Passed Assistant Surgeon.* — Detailed for special duty at Berlin, Germany, January 26, 1891.

GROENEVELT, J. F., *Assistant Surgeon.*—To proceed to Cape Charles Quarantine for temporary duty, February 7, 1891.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL ARTICLES.

A CASE OF EPILEPSY WITH DOUBLE CONSCIOUSNESS.

BY G. R. TROWBRIDGE, M.D.,
ASSISTANT PHYSICIAN TO THE STATE HOSPITAL FOR THE INSANE, DANVILLE, PA.

"DOUBLE consciousness" being regarded by most writers as a strange phenomenon, especially when associated with epilepsy, the following case is deserving of a short report. I regret that the history of the case is somewhat meagre, but I will give the data as completely as possible.

The patient is a German, male, aged fifty-two years, admitted February 3, 1888—his second admission to the hospital. He is about 5 feet 8 inches in height, weighs about 150 pounds, and is thick-set, and very muscular. All of his toes have been lost, and his fingers more or less disabled by frost-bite. He has been subject to epileptic convulsions since 1862, and was first attacked while working on a transatlantic steamer, where he was a stoker. He thinks that the disease was caused by the intense heat to which he was exposed. There is no family history of epilepsy or of any other nervous affection, and no record of insanity. The epileptic attacks are of a most violent nature (*grand mal*), and occur about once every month or six weeks. He then has from three to six convulsions, and never during the time he has been in my charge has he had single convulsions in the intervals. For several days preceding the convulsions he complains of pain in the left inguinal region, and says that it is "due to a fall he had when on board ship." There is no evidence of anything abnormal in this region, and I regard the pain as an aura, as he never complains of it except just before the attack. Shortly after this aura (from twenty-four to thirty-six hours) he has a convulsion, and on recovering from this becomes somewhat irritable and sullen. Other convulsions follow until he has had from three to six. His irritability and sullenness increase in proportion to the number of convulsions, and he finally lapses into a perfect condition of double identity, the original *ego* being completely destroyed, and during this period of second self it is necessary to place him in seclusion.

The time occupied during the transition from the first condition to the second is from two to four days, varying according to the interval between the epileptic attacks.

During this period of "second self" he becomes very violent and abusive, and can be approached only after being physically overpowered. When he passes into this condition he at first refuses nourishment, but toward the latter part of the period he will swallow if a cup is held to his mouth, though it is necessary to restrain his hands and feet. If left to himself he is, as a rule, comparatively quiet, and, as far as I can ascertain, his sleep is not disturbed.

This condition lasts from five to ten days, and his return to a normal condition rarely occupies more than twenty-four hours, though on one or two occasions it has taken somewhat longer. For some time after the return to his normal condition he speaks in a husky voice, and complains that his throat is sore, and for some days he is abstracted and listless.

When in his normal condition, the man is of a pleasant disposition, and does a great deal of work about the ward. When questioned in regard to his sensations during the periods of "second self," he says he can tell nothing except that everybody and everything is strange to him, and that he knows nothing of what he says or does. But he can describe circumstances and occurrences which took place *before* the development of his "second condition"—*i. e.*, during a previous normal period.

The expression of his face during the period of "second self" is altered, changing from a rather pleasant expression to one of intense anger and hatred. In short, I do not think that Stevenson's "Dr. Jekyll and Mr. Hyde" could be worse than this man, were he given his liberty.

On one occasion, before his admission to this hospital, while in his second state, he was disturbed by his wife, who endeavored to make him eat, and in the paroxysm of rage caused by this he tried to kill her with a hatchet, but was prevented by the timely interference of the neighbors. He afterward said that he had no recollection at all of the matter.

It is difficult to understand the changes in the mind of an individual which produce such a phenomenon as double consciousness, and it is hard to explain how the absolute *ego* can be so completely destroyed for the time being. Undoubtedly the epilepsy is the cause of the transition in this particular case, but how it so overwhelms a man's being as to render his own identity *nil*, is to me unexplainable.

Epileptic convulsions occurring in rapid succession will, for a time, destroy the action of the intellectual centres, and for a short time after such an attack it is common for the person to be either violently excited or correspondingly depressed, but never before have I seen a case in which there was complete loss of identity. Spitzka[1] regards this

[1] Manual of Insanity.

condition as one of extreme rarity, and says, "it appears to be limited to the mental disturbances of menstruation and to periodical insanity." He also intimates that such a condition may occur in connection with primary confusional insanity, in regard to which he says:

"It is noteworthy that a large number of the patients are aware that a change has taken place, that they are no longer their former selves, and they may be able to give—by snatches, it is true—a tolerably fair account of the circumstances preceding the outbreak of the disease. But as the latter develops, the patients cease to recognize their position, or to complain of the 'head trouble,' whose existence they previously admitted, and, at most, they speak of their former selves in the third person, or manifest a confused variety of double consciousness."

In defining double consciousness the same author says:

"This condition is characterized by the alternation of periods, in which the subject enjoys his memory and retains his sense of identity, with others, in which he fails to recollect the impressions of his healthy period, but possesses the faculty of learning new ones. In the next healthy period he recollects what occurred before the abnormal period, but does not reproduce every fact acquired in the other. In fact, the mental life of two distinct individuals seems to alternate in one person."

Savage, in his work on insanity, maintains that double consciousness may be present with epilepsy, and also claims that the condition is closely allied to somnambulism.

A large number of cases of double consciousness presenting interesting facts have, from time to time, been reported, and in all the reports that I have seen the period of the second identity was longer than in my case.

The interesting facts in this case are:

First. The association of epilepsy and double consciousness; and

Second. The almost unvarying periodicity and uniformity of the convulsions and sequelæ.

I may say, in conclusion, that various forms of treatment have been tried to prevent these epileptic seizures, but without success.

A CASE OF GUNSHOT WOUND OF THE HEAD, WITH GREAT LOSS OF SUBSTANCE.[1]

BY J. D. GRIFFITH, M.D.,
PROFESSOR OF SURGERY IN THE KANSAS CITY MEDICAL COLLEGE.

[Reported by B. VAN SWERINGEN, M.D.]

THE patient was a boy sixteen years of age, a native of this country, who on June 8, 1888, while playing with his mates, was accidentally shot in the head. The weapon was an old style Colt's revolver 0.38 calibre, and was fired at a distance of not more than two feet. The bullet entered just above the middle of the right superciliary ridge and passed out through the upper right segment of the occipital bone, wounding in its course the anterior, middle, and posterior lobes of the cerebrum.

Dr. Crow called me to see the case, and when I arrived, two hours after the injury, the patient was lying on his right side, comatose, bleeding from the points of entrance and exit, particularly from the former, and also apparently from the right ear. He had complete hemiplegia on the left side, but no paralysis on the right. The pupil of the right eye was markedly dilated, and that of the left contracted; there also existed a very slight converging strabismus, which his parents assured me was present before the injury. The patient, of course, presented the symptoms of profound shock, and his death was momentarily expected. However, we shaved his head and joined the openings made by the ball, by an incision about seven and one-half inches in length. Upon separating the edges of wound, we found that the frontal, the parietal, the greater wing of the sphenoid, the squamous portion of the temporal, and a portion of the occipital bones had been shattered; the largest piece of bone that came away being about two and one-half by three inches. We carefully removed all the fragments, following as nearly as possible the rules of asepsis, if not antisepsis. After the numerous fragments of bone had been removed, we found the opening in the dura opposite the point of entrance, and also the wound of exit, which was the larger; these we enlarged, nearly joining them. The track of the ball was easily found, along which were discovered a number of spiculæ of bone which had been carried in by the ball. Upon washing these out, at least two ounces of cerebral substance escaped.

We then inserted a drainage-tube from the entrance to the exit, leaving a half inch of the tube projecting in front and behind, closed the wound with catgut, and applied an antiseptic dressing.

His symptoms grew no worse during the operation, and he even showed signs of returning consciousness by wincing from the pain when the sutures were introduced. On the next morning the boy was perfectly conscious and his memory seemed to be perfect. We tested his mental faculties by requiring him to add figures, etc., which he did with readiness in various ways. His memory for events before the accident is seemingly as good as ever, and there is no reason to believe that it has since failed, for he remembers everything from the time he regained consciousness after the operation. After the operation there was present, in addition to the hemiplegia, marked stuttering, which has steadily diminished. This was in all probability due to extensive loss of cerebral cortex.

Two weeks after the injury the boy had a chill, and upon close examination I found a small collection of pus below the wound of exit in the occipital bone. This I opened and drained. Six weeks after the injury a hernia cerebri made its appearance, and became fully as large as my fist. When this was firmly pressed upon, as by a bandage in order to reduce it, coma followed; I, therefore, allowed it to be gradually reduced by the pressure of the head against the pillow.

A small bed-sore was the only other complication,

[1] Read before the Kansas City Academy of Medicine.

but this gave very little trouble. Marked depression and a large cicatrix now mark the seat of the wound. From the point of entrance, about half an inch above the middle of the right superciliary ridge, to the point of exit, about half an inch below the parietal occipital suture, and from the saggital suture to the temporal ridge there is entire absence of bony structures. At its greatest depth the depression measures a little over an inch.

Sensation in the paralyzed side began to reappear six weeks after the injury, the skin becoming sensitive to pain down to the elbow and to the knee. There is still slight numbness below those points. Motion also developed with returning sensibility, and has been greatly benefited by electricity. In November he made his first attempt after the injury to walk, and he is now able to walk without assistance. The flexor muscles of both the upper and lower extremities are stronger than the extensor muscles. It is difficult for him to lift the toes of the left foot from the ground, and there is an inclination for this foot to catch on the other. When he tries to open his hand to grasp anything the flexors are thrown into a spasm, which causes his hand to close tighter.

His temperature for two weeks after the operation remained between 98½° and 100½°. Whenever it rose above 99° an ice-bag was applied to his head.

Regarding the converging strabismus, I am inclined to accept the statements of his parents, that it existed prior to the accident, for I do not see how it would be possible for the fibres of the motor-oculi supplying the internal rectus to have been injured and the remainder of the nerve escape, and if the entire nerve had been injured the other ocular muscles would have been affected. There may be some difference in the size of the pupils, and I think there is a difference in their response to light, but there is no hemianopsia and the eye-grounds seem to be normal.

The boy is now going to school, and is progressing in his studies without evidence of impaired mental faculties. It would be interesting to know whether it is only the left hemisphere that is doing the work. No medical treatment has been employed. He comes to the office so that we may keep the muscles developed and improve their condition, if possible, by the battery.

DISCUSSION.

In discussing this report DR. S. G. BURNETT said that he had seen but one similar case. In that case a man had a drill blown with great force into his head. It entered just anterior to the ear, passing upward and removing a considerable portion of the motor tract. The patient had complete hemiplegia for a time, but recovered with fairly good use of his left side. A peculiar thing in this case was paralysis of the soft palate, which occasionally seemed to drop down and almost strangle the man.

One important and singular point about Dr. Griffith's case is that he had no convulsions. This the speaker could explain only by supposing that the whole of the motor centres was destroyed, so that no irritation could be received by the cortical substance. The boy has the characteristic hemiplegic gait, and that peculiar grasping of objects followed by inability to relax the grasp, which is also very characteristic. This condition is to be expected, because normally the flexors are more powerful than the extensors.

The stuttering is probably due to incoördination. All authorities claim that the speech-centre is on the left side of the brain, and undoubtedly, if the injury had been on the left side, there would have been complete aphasia. His intelligence is very good, better than we would expect, but just what amount of brain tissue has been removed cannot be estimated. The speaker did not think it possible to have paralysis of the internal rectus without a similar loss of power in all the muscles supplied by that nerve. There could not be complete motor destruction without implication of the third nerve.

DR. B. E. FRYER said that the appearance of the wound seemed to indicate that it was made by a round, instead of a conical bullet; still conical bullets sometimes play terrible havoc, as in this case. The case was very interesting, both surgically and neurologically. Surgically, it is a demonstration of what boldness, with care and activity, will do in these cases, plus the antiseptic methods.

An important point, which is not sufficiently referred to, is that in such injuries spiculæ of bone are carried into the brain.

Dr. Fryer had seen the case of a man who died very suddenly while apparently in good health, His duties had required severe work, and he was fairly intelligent. The disease of which he died seemed to be a sudden attack of pneumonia. The speaker's assistant, an accurate observer, made the post-mortem, and found the whole of the right frontal lobe a pultaceous mass, a condition that must have existed for months. This corroborated what Dr. Burnett said in regard to the speech-centre being on the left side; it shows that intellectuality and mentality may not be dependent upon the bilateral working of the brain, for this man had shown no signs of mental failure in the months during which he had been under observation.

DR. JOHN PUNTON said that the case opened for consideration the subject of cerebral localization.

Thomas Hood, of London, in 1822, reported cases and stated that disturbances of speech always accompany lesions of the frontal lobe; this was proven by Broca in 1861, when he definitely localized the speech-centre as being in the lower portion of the third frontal convolution on the left side. Dr. Griffith's case seems to confirm that report.

In 1872, Ferrier made experiments which demonstrated that the anterior portion of the brain is concerned only in motor acts, while the posterior is devoted to receiving sensory impressions, and the case reported seems to support these views also. In the first place there is left hemiplegia; that would, of course, support the theory that the fibres of the motor tract cross to the opposite side. Now the motor zone is situated at, and includes both sides of the fissure of Rolando, for a distance of about an inch, including a portion of the frontal, parietal, and paracentral lobes; that is, the ascending frontal, the ascending parietal and the anterior portion of the superior parietal convolutions. It would seem that all of these parts were more or less injured in this case.

There are at least three different schools of experimental physiologists in cerebral localization. One school is represented by such men as Monk and Ferrier, who believe the brain can be mapped out into definite areas whose limits and function can be clearly defined. Another school, represented by Exner and Luciani, oppose the sharply-defined boundaries of definite areas and claim that they overlap to a greater or less extent. The third school, represented by Brown-Séquard and Golz, of Strasbourg, still support the original view of Flourens that the brain can act only as a whole. Now it is very difficult at times for the student to know which school to follow.

This case seems to overthrow theories that were thought to be conclusively proven.

The cause of the spastic contraction is probably due to irritation caused by the cicatrix at the angle of junction of the superior parietal and ascending parietal convolutions, and if an operation for its relief should be deemed expedient, that should be the objective point, but *any* operation would hardly be warranted.

DR. B. H. ZWART referred to the following case of his own:

In one of the battles of the civil war a man named Stewart lost the upper part of his head, and a considerable amount of brain-substance. For a year following he was confined to his bed, owing to complete paraplegia. This, however, gradually grew better, and he became addicted to the use of liquor, and after an excessive indulgence he became very nervous, and finally, in 1876, convulsions supervened. He died of phthisis some years later. The fact that the convulsions came on so late may throw some light on the future history of Dr. Griffith's case.

DR. B. E. FRYER thought that an injury of this kind does not militate against any of the established views in regard to cerebral localization. It must be remembered that we have not a clean cut through the brain. A conical ball distorts the skull, and lacerates the brain. Moreover, there is a scattering of the bone along the track of the ball. We cannot, therefore, lay down rules except by symptoms, and he thought that the symptoms in this case were definite, and conformed, in the main, to the theories in regard to localization. Again, we have more or less hæmorrhage into the brain after such injuries, which further obscures the diagnosis. It is very difficult, therefore, to know to just what extent the brain has been damaged after such an injury as this.

DR. KYGER said that two things in this case struck him very forcibly: one was the boldness of the surgeon in operating while expecting the momentary death of the patient; the other was the value of antisepsis.

DR. FEE said that the question of drainage and of the kind of drainage, whether strands of catgut, or rubber, or glass tubing, etc., was a matter of personal experience. Drainage has been abused. Too large drainage-tubes are left in place too long, and act as foreign bodies.

DR. BURNETT said, in regard to the application of electricity, that the proper way to apply it would be to place one electrode over the back of the neck, moving the other over the body, and using a current strong enough to cause contractions.

DR. PUNTON asked Dr. Burnett if he thought the case would terminate in Jacksonian epilepsy.

DR. BURNETT thought that it would not, because there is so little gray matter left; but as there is some dizziness, and contractions when the boy becomes excited, epilepsy may develop.

DR. GRIFFITH, in closing, said that he had almost decided, that in case marked epileptic seizures developed, to operate on the cicatrix. Whether anything could be accomplished by celluloid implantation, or whether it would be successful, could not be determined. If something of that nature could be done it would be of advantage, by lifting the scalp away from the encephalon. The paroxysms of dizziness under excitement are disappearing.

In reference to drainage-tubes, in this case a tube as large as the little finger was used, and kept in for thirty-two days, but it was kept clean, and was not removed until no débris came from it. For the first two weeks a great deal of broken-down material came away. He thought, however, that the tube was kept in too long, and was probably instrumental in causing the hernia cerebri which developed at the point of exit of the drainage-tube after its removal.

THE SURGICAL TREATMENT OF EMPYÆMA.[1]

BY JAMES A. GOGGANS, M.D.,
OF ALEXANDER CITY, ALA.;
SENIOR COUNCILLOR OF THE MEDICAL ASSOCIATION OF THE STATE OF ALABAMA.

DURING the last eighteen months I have treated six cases of empyæma following pneumonia, all of which have made perfect recoveries. The patients varied in age from three to thirty-five years. I reported the clinical histories of three of the cases in a paper read before the Southern Surgical and Gynecological Association in 1889, and I trust that, in presenting them again in connection with others, they will not fail to be interesting. Besides, every case of empyæma presents its own clinical phenomena, consequently no single line of treatment can be invariably adhered to. It is a disease that any practitioner of medicine is likely to encounter, and with which we must deal promptly; therefore much more valuable information may yet be acquired by carefully studying the clinical history of each case.

The plan of treatment known as the surgical treatment is the one which has always been most successfully employed. Spontaneous cures are so rare that surgical interference is the rule. Powell has well said, and nearly all writers concur with him, that

"the spontaneous disappearance of such effusions is too uncommon to be expected, and the process of reabsorption is one too full of peril to be anticipated with anything but dread. It is indeed an attempt at such absorption that occasions the most characteristic hectic symptoms. Consequently the prognosis is practically hopeless without surgical interference. We must adopt some surgical measures or take upon ourselves the responsibility for a large mortality."

[1] Read before the Southern Surgical and Gynecological Association, November 13, 1890.

There are many modes of operating for the removal of pus from the pleural cavity, but they may be classified as follows under two general headings:

First. The closed method, which consists in removing the pus by simple puncture with a trocar or an aspirator-needle, and allowing the puncture to heal at once. This method was taught in the school of Hippocrates and described in the writings of Galen, but, until quite recently, was practised only as a last resort.

Second. The open method, which consists in making a more or less free incision and the introduction of a drainage-tube to maintain the perfect evacuation of the fluid, to permit irrigation, and to promote free ingress and egress of air that has passed through an antiseptic dressing. The surgical treatment then being an absolute necessity, we cannot over-estimate the importance of making the diagnosis certain by resorting to exploratory puncture with a hypodermic syringe. We can assure the patient that no harm can result from the procedure, and that the prognosis depends upon this means of settling the diagnosis.

In performing thoracentesis, some form of modern aspirator should be used. The patient should be prepared for the operation by administering an alcoholic stimulant, and, if an adult, a dose of morphine hypodermically; if a child, the camphorated tincture of opium by the mouth. By these measures the shock, caused by the introduction of the needle, is diminished, as are the cough, pain, and dyspnœa, which are so liable to follow the sudden withdrawal of the fluid and the subsequent expansion of the lung. The needle should be thoroughly cleansed and disinfected, and the point on the chest-walls at which the puncture is to be made should be thoroughly scrubbed with soap and water and bathed with an antiseptic solution. An anæsthetic cannot be considered as absolutely necessary.

J. Lewis Smith and a few other writers do not think that it is necessary to remove all the pus, but I think that we should remove as much as is possible, lest fistulous openings be formed through the walls of the chest, or through the lungs. Still it should not all be removed, if pain and dyspnœa be complained of, for the operation can be completed on the next day or within a few days.

I have performed thoracentesis one hundred and sixty-eight times, and have had no trouble from it, except slight pain and temporary dyspnœa.

As to the number of aspirations that should be made before resorting to the open method, there are many different opinions. I think, however, that the decision should depend almost entirely upon the character of the fluid and the physical condition of the patient. To illustrate this, I will refer to my own cases. The first case, aged seven years, was cured after eleven aspirations. The second, aged seventeen years, after one aspiration. The third, a man thirty-five years of age, after two aspirations. The remaining three were not cured by aspiration; one of them, aged twenty years, was aspirated seventy-three times; another, aged three years, was aspirated ten times; and the last one, aged eight years, was aspirated seventeen times before thoracotomy was performed. It is stated by almost all writers that when the fluid becomes fœtid incisions should be made, and I believe that the character of the fluid should govern us, to a great extent, as to when we should abandon thoracentesis and resort to thoracotomy. Still, in one of my cases, the pus was fœtid at the forty-fifth aspiration, and the fœtor had disappeared at the forty-ninth. The physical condition of this patient, while the pus was fœtid, was in no way worse than it was just before or afterward, and, as has been stated, aspiration was done seventy-three times before thoracotomy was performed. This record, in connection with the opinion of other operators, is certainly sufficient to establish the fact that thoracentesis should always be given a fair trial in any case of purulent pleurisy, before the open method is resorted to.

During thoracentesis the sitting posture must be assumed by the patient, unless there is great feebleness, when the recumbent posture may be allowed. I removed thirty-two ounces of pus from one of my patients while he was in the recumbent posture, the needle being introduced between the fourth and fifth ribs in front. The pus seemed to flow as rapidly as though the patient were in the erect position.

I wish to call special attention to the condition of patients just after the operation of thoracentesis. The histories of my cases illustrate this condition very forcibly, nevertheless I mention it here. Take, for example, a patient aged from three to eight years, with the physical signs of empyæma, a temperature of 103° F., pulse from 120 to 160, and the respirations from 30 to 60 per minute. Remove the pus by aspiration, and the following morning the temperature will be very near the normal standard, or perhaps a little subnormal, and, if recovery is to take place from this operation, the pulse and respirations will also be very nearly normal, with but slight elevation on the following evening. If, however, there is to be a re-accumulation of the pus, and hence a necessity for repeating the aspiration, the temperature will be nearly normal or perhaps subnormal, but the pulse will remain at from 100 to 130, and the respirations from 40 to 60 per minute. From observations made during the progress of my cases, I have found that the rapid respiratory movement is the last symptom to disappear, and that there is no certainty in the success

of the operation until the pulse and respirations fall with the temperature.

The three cases cured by aspiration had a pleuro-bronchial fistula, and two of them expectorated large quantities of pus. The third never expectorated pus, but there was always considerable escape of air into the aspirator after the pus had ceased to flow, proving that a pleuro-bronchial fistula existed. In one of these cases, aged thirty-five years, the right arm was elevated during the operation, thereby elevating the scapula from its normal position, and the needle was introduced between the sixth and seventh ribs under the scapula, consequently, when the arm was lowered the scapula descended and covered the puncture made by the needle through the subscapular tissues.

The physical condition of the patient should be our principal guide in resorting to the operation of thoracotomy. In other words, thoracentesis should be adhered to, unless we see great emaciation and hectic symptoms. Another condition under which I would urge the operation of thoracotomy, is where perforations through the lung are threatened, since the most serious complication of empyæma is a pleuro-bronchial fistula.

In order to perform the operation of thoracotomy a general anæsthetic must be used. I am partial to ether carried to complete anæsthesia. The operation can then be performed carefully, the drainage-tubes adjusted with precision, and the antiseptic dressing applied without inflicting pain. The point selected for making the incision should be thoroughly cleansed, the tissues divided down to the pleura with a bistoury and a grooved director thrust into the pleural cavity, when the pus will begin to escape along the groove. The incision should then be made large enough in the adult to admit the index-finger, and in children lengthened to the extent of at least one inch to permit free escape, not only of the fluid, but of any fibrous masses or organic débris that may be present, which are apt to undergo decomposition and thereby produce septicæmia and death.

It is stated by almost all authors that there is no danger of the pus escaping too rapidly, since air will enter in its place and equalize the pressure. I have not found this to be true. In two of my cases I was forced to close the incision and stop the flow of pus by introducing my finger, and subsequently a tent, to relieve the cough and dyspnœa brought on by the sudden withdrawal of the fluid. This being the case, I think that it would be extremely hazardous suddenly to evacuate the fluid by incision, and immediately irrigate the pleural cavity, even if the pus were fœtid. The success of the operation depends upon the free ingress and egress of air that has passed through an antiseptic dressing, and it should be plainly heard passing through the tubes at each act of forced expiration.

The object of using irrigation is said to be to rid more completely the pleural cavity of the elements of decomposition, and thereby favor obliteration of the abscess cavity, by allowing the pleural surfaces to grow together by granulation. Therefore, if irrigations are employed, it is very important to use no force in carrying the fluid into the pleural cavity, since delicate and important granulations and adhesions may be broken up.

As soon after the operation as the condition of the patient will permit, two pieces of one-fourth inch drainage-tube should be introduced in such a manner as merely to project into the pleural cavity, and cut off about one-fourth of an inch from the external surface of the chest; then the antiseptic gauze dressing should be applied.

If the ribs are so close together that drainage cannot be maintained through a simple incision and rubber tubes, or if, from inexpansiveness of the lung or any other cause, the pleural cavity fails to become obliterated, the old operation of resection of ribs affords the best chances for thorough evacuation of the fluid and subsequent drainage.

At a recent meeting of the German Congress of Internal Medicine, the surgical treatment of empyæma was pretty thoroughly discussed, and to show the general plan adopted by those who took part in the discussion, I will give a synopsis of what was said:

"In the first place, it was agreed by all that some kind of surgical interference was indicated, except in very rare instances.

"Professor Immermann opened the discussion and stated, first of all, that the pus must be evacuated by operation; and next, that simple aspiration will not answer except in small empyæmata, which of themselves would become absorbed. The plan recommended by Bulau was spoken of most favorably. Immermann collected 49 complete cures out of 57 cases. It was not suitable, however, for cases of inexpansive lung, pyopneumo-thorax, or pulmonary fistulæ.

"Dr. Schede, of Hamburg, took the surgeon's view of the matter, and advised the radical operation, *i. e.*, resection of rib. Bulau's operation he thought much less safe than resection.

"Dr. Curschmann, of Leipsic, has treated all cases in the past ten years by Bulau's method. Among 73 cases 89 per cent. were cured and 6 died.

"Professor Leyden spoke favorably of Bulau's method.

"Dr. Ewald, in 1874, had collected statistics in Frerich's clinic of 109 serous and 46 purulent cases, and had then concluded that of 1000 cases 928 do not get well with simple puncture, while 528 are cured by radical operation. The results of surgery to-day are much better than that. In the present year he had, with Koster, operated with the double incision in 9 cases, with 1 death from rapid tuberculosis. The operation was done as soon as the nature of the case was proved. The objections arising from the old cases would be obviated if early interference were the rule.

"Professor von Ziemssen, of Munich, had for ten years past treated all empyæmata by incision and rib resection, and was perfectly satisfied with this method.

"Dr. Mosler, of Greifswald, advised, after the operation, washings with boric acid, and then injections of iodoform and glycerin.

"Dr. Runeberg, of Helsingfors, treated all empyæmata by rib resection, and did not wash out. He had thus dealt with 63 cases, of which two were still under treatment. Two were manifestly tuberculous, 10 were due to pulmonary gangrene, 49 were simple empyæmata. Of these latter, 46 were completely healed, in 2 fistulæ remained, 1 case died from erysipelas. The average duration of treatment was forty-eight days.

"It will be noticed that the opinions of all who took part in the discussion were divided between Bulau's method and rib resection. Simple incision with the introduction of drainage-tubes was not advocated by any of them. Nearly all thought that injections were useless."[1]

Now, the plan of making free incisions and introducing drainage-tubes is frequently successful in this country, and I do not believe that rib resection should ever be resorted to, except in cases in which perfect drainage with free ingress and egress of air fails to be accomplished by simple incision, and in cases in which the cavity fails to become obliterated, from an inexpansive lung or from any other cause. In such cases the removal of a considerable portion of rib weakens the thoracic walls, and thereby favors retraction of the chest and obliteration of the pus-cavity.

In all of my cases it was evident that the pleural cavity was almost obliterated within the first two or three days after thoracotomy was performed, and, instead of producing dyspnœa and cyanosis, these symptoms rapidly disappeared after the operation.

I am satisfied that irrigations cannot be used with safety, since there have been many instances of sudden death directly attributable to them. Loomis states that he has thrice had good reason to attribute sudden death to the direct effect of washings. Sir Joseph Lister also advises against irrigation. Consequently I do not believe that it should be practised unless there are symptoms especially demanding it. It is admissible when the discharge is very chronic, and continues in spite of free drainage, and when there are symptoms which threaten septicæmia. I used irrigations of warm water in all of my cases, and am convinced that they are irritating and injurious during the first two or three weeks following the operation.

In one of my cases, aged twenty-one years, the tube accidentally dropped out too early, and there was a re-accumulation of the pus and enlargement of the abscess cavity. Weak solutions of iodine (four or five grammes each of iodine and iodide of potassium to the pint of warm water that had been boiled) proved to be very beneficial. The discharge was checked at once, and the pus-cavity quickly obliterated.

[1] Medical Record.

To illustrate the subject further, I will report the following cases:

CASE I.—Carl R., male, aged seven years. Had influenza, complicated by pneumonia, in March, 1889. On April 27th, pulse 98, temperature 99½°, decided dulness over the right side of the chest. Removed by aspiration 4 ounces of pus.

May 2. Pulse 102, temperature 102½°; removed 8 ounces of pus from between seventh and eighth ribs in the axillary line.

5th. 9 A. M., pulse 110, temperature 99⅕°; has considerable cough with some expectoration; removed 4 ounces of pus.

8th. Pulse 115, temperature 100⅘°; removed 6 ounces of pus.

9th. Pulse 76, temperature 98°, respirations 36; slept well last night, calls for food.

10th. Pulse 100, temperature 99⅗°; removed 3 ounces of pus.

11th. Pulse 96, temperature 98⅖°, respirations 36; takes plenty of nourishment.

12th. Pulse 100, temperature 99½°; has taken too much food and is passing blood from the bowels.

15th. Pulse 110, temperature 99⅖°, respirations 40; removed 1 ounce of pus.

17th. Pulse 115, temperature 102⅕°, respirations 40; removed 3½ ounces of pus.

18th. Pulse 100, temperature 99°; much more comfortable.

19th. Pulse 118, temperature 102⅗°; removed 3 ounces of very thick pus.

21st. Pulse 90, temperature 98½°, respirations 30; removed 1 ounce of pus.

23d. Pulse 120, temperature 100⅕°; removed 1 ounce of thick pus.

28th. Pulse 100, temperature 98⅗°, respirations 24.

30th. Pulse 84, temperature 98, respirations 22. From this time he made a rapid and complete recovery. There were in all eleven operations performed, and at each operation air escaped freely into the aspirator through a pleuro-bronchial fistula after the pus had ceased to flow.

CASE II.—E. R., male, aged seventeen years. Had influenza and pneumonia, followed by abscess of the lung, which discharged large quantities of pus by expectoration, from April 10 to May 28, 1889. On May 29th cough had entirely ceased, pulse 110, temperature 100°; circumscribed dulness over the abscess cavity about the middle of the left side of chest. Removed by aspiration about six ounces of very offensive pus—all that would flow through the instrument. There was no cough or distress of any kind when the operation was completed, but cough began in an hour afterward, and he expectorated eight or ten ounces of very offensive pus within the next twelve hours.

May 30. 8 A. M., pulse 88, temperature 98½°; expectoration has entirely ceased and the patient is very comfortable.

30th. 7 P. M., pulse 84, temperature 97⅕°; still no expectoration. Great retraction of the chest-walls in the locality of the abscess.

June 8. Pulse 80, temperature 98½°.

He made a complete recovery.

CASE III.—W. R., male, aged twenty years. Had influenza, and on March 16, 1889, had a chill followed by pneumonia of the right lung. There was no decided crisis, and on April 12th I removed 13 ounces of pus from between the seventh and eighth ribs in the axillary line. At this time his pulse was 92, temperature 101°, respirations 30. The cough had ceased. When the thirteen ounces of pus were removed he had some pain and dyspnœa, and the operation was ended.

April 14. Pulse 90, temperature 99⅕°. Has slept well since the operation.

15th. Pulse 96, temperature 99⅕°. Is obliged to take morphine to procure sleep. I removed 6 ounces of pus, when the operation had to be terminated.

16th. Pulse 84, temperature 99⅘°. Has slept well since the operation.

18th. Pulse 92, temperature 100°, respirations 50; symptoms of re-accumulation. Removed 32 ounces of pus; the puncture was made in front, between the fourth and fifth ribs, the patient lying on the back.

19th. Pulse 80, temperature 98½°, respirations 22. Is very comfortable.

July 15. Forty-five aspirations have been performed, and 351 ounces of pus have been removed.

16th. I removed 8 ounces of very offensive pus. Thoracotomy advised, but the patient would not consent to the operation.

When the forty-ninth operation was performed the fœtor had entirely disappeared. Aspiration was repeated until the seventy-third operation, when 500 ounces of pus had been removed.

September 14. Pulse 112, temperature 98⅘°. The operation of thoracotomy was performed, ice being used as a local anæsthetic. The incision was made in front because the pus was pointing there. Five or six ounces of pus escaped, a soft rubber drainage-tube was introduced, and the dressing applied, which consisted of several layers of antiseptic gauze. About 2 ounces of pus were discharged daily until October 1st. At this time his pulse was 110, temperature 100°, and I commenced to irrigate the abscess cavity.

November 1. Pus cavity has been irrigated since October 1st, and now holds only a drachm or two of fluid.

8th. The tube is still in place and the patient is able to walk a mile or two. From this time he made a complete recovery.

CASE IV.—John G., male, aged thirty-five years. Developed pneumonia on April 10, 1890. I saw him in consultation with Dr. G. C. Radford on May 22d. He then had been expectorating large quantities of pus. His temperature on May 20th and 21st, was 102°; when I saw him his temperature was 98½°, pulse 84, and respirations 24. There was circumscribed dulness about the lower angle of the scapula; I elevated the scapula and removed 5 ounces of pus from between sixth and seventh ribs.

May 23. Temperature 100°, pulse 72, respirations 22.

24th. Temperature 99°, pulse 72, respirations 22; removed 12 ounces of pus from under lower angle of the scapula. No distress of any kind followed the operation.

June 1. Temperature 98½°, pulse 85. On June 4th and 5th, he expectorated a considerable quantity of pus.

8th. Temperature 98½, pulse 72, respirations 20. From this time he made a complete recovery.

CASE V.—Katie W., female, aged three years, was taken with pneumonia on February 13, 1890. I saw her in consultation with Dr. Onslow Regan on March 29th, temperature 102°, pulse 140, respirations 40. I removed 7 ounces of pus by aspiration.

March 30. Temperature 97½°, pulse 112, respirations 40.

31st. Temperature 101½°, pulse 130, respirations 48. Removed 5 ounces.

April 1. Temperature 98½°, pulse 104, respirations 36; patient comfortable and playful.

3d. Temperature 103°, pulse 150, respirations 50. Removed 6 ounces of thin pus.

5th. Temperature 97°, pulse 110, respirations 40; patient very comfortable.

6th. Temperature 101°, pulse 150, respirations 50. Removed 6 ounces of pus from between the fifth and sixth ribs, in the axillary line.

7th. Temperature 98½°, pulse 120, respirations 36.

11th. Temperature 101½°, pulse 140, respirations 48; considerable cough and expectoration, but patient swallows the pus.

13th. Temperature 102°, pulse 140, respirations 48.

15th. Temperature 98½°, pulse 120, respirations 40; expectorating and swallowing large quantities of pus. Pus-cavity completely emptied by the pleuro-bronchial fistula.

19th. Temperature 101°, pulse 140, respirations 48; expectoration has ceased, and there are evidences of re-accumulation of pus in the pleural cavity; I removed by aspiration 18 ounces of pus.

20th, 9 A. M. Temperature 99°, pulse 130, respirations 30. 6 P. M. Temperature 100°, pulse 130, respirations 50; considerable cough, but no expectoration. Eleven operations have been performed, and air escaped freely into the aspirator through a pleuro-bronchial fistula, after the pus had ceased to flow, at each operation.

Performed thoracotomy under ether carried to complete anæsthesia. Incision made in the axillary line between the sixth and seventh ribs. About one pint of pus escaped, air was freely admitted in its place, but cough and dyspnœa supervened, and a tent was introduced to prevent complete evacuation of the fluid.

21st. Temperature 98½°, pulse 120, respirations 30; removed the tent, and one pint of pus escaped. A single one-quarter-inch soft-rubber drainage-tube was introduced, a dressing applied, and air freely admitted.

24th. Temperature 98°, pulse 120, respirations 24.

26th. Temperature 98°, pulse 120, respirations 24; has dysentery, caused by having swallowed the pus.

May 1. Temperature 98½°, pulse 120, respira-

tions 24; about 1 ounce of pus is being discharged per day through the tube.

6th. Temperature 98½°, pulse 120, respirations 24; only 2 or 3 drachms of pus escaping per day.

10th. Temperature 98½°, pulse 120, respirations 24; very comfortable; was carried on the streets in her carriage.

31st. Temperature 98½°, pulse 120, respirations 24; pus-cavity has been irrigated since May 17th; now discharging 1 ounce of pus per day; washings discontinued.

June 8. Temperature 98½°, pulse 120, respiration 24; has been able to stand on her feet for several days; still wearing the tube.

17th. Tube removed, and patient discharged cured.

CASE VI.—Maxwell G., male, aged eight years, was taken sick with pneumonia, March 23, 1890. There was no decided crisis, and on the fourteenth day after the chill his temperature was 100°, pulse 130, respirations 48.

April 6. Temperature 101°, pulse 120, respirations 40.

7th. Temperature 100½°, pulse 125, respirations 50. Removed 6 ounces of pus by aspiration from the right pleural cavity; the needle was introduced between the fifth and sixth ribs in the axillary line.

9th. Temperature 100°, pulse 130, respirations 48. Removed 3 ounces of pus.

10th. Temperature 99°, pulse 125, respirations 40.

12th. Temperature 101°, pulse 130, respirations 48. Removed 4 ounces of pus.

13th. Temperature 99°, pulse 120, respirations 36.

14th. Temperature 102½°, pulse 130, respirations 48. Removed 2 ounces of pus.

15th. Temperature 98⅘°, pulse 116, respirations 36.

17th. Temperature 101⅘°, pulse 120, respirations 48. Removed 4 ounces of pus.

18th. Temperature 98½°, pulse 100, respirations 40.

20th. Temperature 100½°, pulse 120, respirations 48. Removed 4 ounces of pus.

26th. Temperature 102°, pulse 130, respirations 50. Removed 2 ounces of pus.

27th. Temperature 99½°, pulse 130, respirations 40.

28th. Temperature 100°, pulse 120, respirations 40. Removed 2 ounces of very thick pus.

May 1. Temperature 98, pulse 112, respirations 32.

6th. Temperature 100°, pulse 120, respirations 48.

9th. Temperature 98½°, pulse 110, respirations 40.

14th. Temperature 99°, pulse 120, respirations 40. Removed 2 ounces of pus.

15th. Temperature 98°, pulse 100, respirations 36.

21st. Temperature 98½°, pulse 132, respirations 50. Removed by aspiration 8 ounces of pus.

22d. Temperature 102½°, pulse 152, respirations 50.

23d, 9 A. M. Temperature 98½°, pulse 120, respirations 40. Performed thoracotomy under complete anæsthesia from ether. A large quantity of pus escaped, together with solid fibrous masses and débris. A severe cough and dyspnœa set in before the pus-cavity was emptied, and the incision was closed by introducing a tent. At 8 P. M., temperature 98½°, pulse 120, respirations 40.

24th. Temperature 98½°, pulse 100, respirations 35. Removed the tent from the incision, when several ounces of thin fluid escaped. Two pieces of one-fourth inch soft-rubber drainage-tube were introduced into the incision side by side.

25th. Temperature 98½°, pulse 90, respirations 32; air passes freely into and out of the pus-cavity through the tubes, and several ounces of serous fluid have escaped.

28th, 9 A. M. Temperature 98½°, pulse 110, respirations 36; 6 P. M., temperature 100°, pulse 130, respirations 48.

June 6. Temperature 98½°, pulse 90, respirations 30; able to sit up in bed.

15th. Up and walking about the room. I removed the tubes. From this time he made a rapid recovery.

In such cases as those reported some time ago by Dr. G. Frank Lydston, in the *Western Medical Reporter,* aspiration would hardly be indicated.

These cases are of a very interesting and exceptional character, and I will briefly report them in Dr. Lydston's own words:

"These cases I observed some years ago at the New York Emigration Hospital, and, for want of a better term, I have called it acute empyæma or acute suppurative pleurisy. The patient, a stout, powerfully-built Scandinavian, was sent to Ward's Island from Castle Garden immediately after landing, and without examination or diagnosis. As my interpreter was absent, I postponed a thorough examination of the patient until the following morning, making the provisional diagnosis of pleurisy with effusion. The temperature was 104° in the axilla. I was called away from the hospital the following morning, and upon my return in the afternoon I found the patient in a dying condition. He lived only an hour after I saw him. On post-mortem examination I was astonished to find the right side of the chest distended with pus of an exceedingly fœtid character; the lung was compressed against the mediastinum. When stripped off it formed a layer not exceeding an inch in thickness. So firmly was it compressed that I was at first at a loss to know what had become of the lung. The purulent fluid nearly filled an ordinary ten-quart milk-pail. All the other organs were in a healthy condition. The patient had only been sick about two weeks, as he was taken ill after getting aboard the steamer bound for America. This case was evidently of an infectious character, and probably the result of secondary infection, but I have no idea as to what might have been the primary difficulty.

"In this case a preliminary tapping would have been good practice, but sooner or later a free incision, with drainage, would have been necessary.

"The second case was that of an elderly woman, who developed empyæma secondary to pleurisy with effusion. The origin of the difficulty was unquestionably tubercular. The effusion subsided readily, but after a few weeks a rise of temperature, chills, and increase of pain heralded the formation of pus. It was about three weeks before I was able to detect the location of the purulent inflammation. I finally, however, mapped out an area of dulness, about the size of a silver dollar, at the level of the

ninth and tenth ribs, about four inches from the spinal column. Aspiration proved the existence of pus. A modified Estlander's operation was performed, with the excision of about two inches of the tenth rib. On passing the finger into the track of the pus it was found to lead to a considerable sacculus between the inner surface of the lung and the mediastinum. Free drainage was instituted, and the cavity closed in about eight weeks. Several months later a swelling appeared upon the thorax at the junction of the third and fourth costal cartilages with the sternum. This finally opened and discharged a considerable quantity of pus. Operation was refused. The patient finally died, apparently from the prolonged suppuration rather than from the tubercular process in the lungs, which, contrary to expectation, progressed very slowly.

"The third case of interest was very similar in some respects to the preceding. The patient, a man of middle age, previously healthy and strong, had been suffering from acute pleurisy for four or five days. On examination I found that tapping was not yet necessary, but suggested that it might be advisable later on. Three weeks later I again saw the patient, but the effusion, which, Dr. Walker informed me, had apparently been considerable, had almost entirely been absorbed. About a week later an irritating cough came on, and the temperature, which had become normal, again rose quite suddenly, but subsided in less than a week. The patient now began to expectorate a fœtid, purulent sputum; diarrhœa also set in. The severe cough and inability to sleep in the recumbent posture proved very annoying.

"On examination I found an area of dulness on percussion in about the same location as in the preceding case, and, bearing this case in mind, I diagnosed sacculated empyæma between the lung and the mediastinum. The same operation was performed as in the preceding case. A large quantity of pus, of a very offensive character, escaped; the odor was that characteristic of rotten eggs. The expectoration of the antiseptic fluid used for irrigation showed that the sacculus communicated with the bronchi. The case has done well since the operation, and is in a fair way to recover. The cough and diarrhœa have improved, and an excellent appetite has developed. As there is no appearance or history of tuberculosis in the case, the prognosis is apparently favorable."

REMARKS ON THE SURGICAL TREATMENT OF FIBROID TUMORS OF THE UTERUS.[1]

BY R. STANSBURY SUTTON, M.D.,
SURGEON TO TERRACE BANK HOSPITAL FOR WOMEN, PITTSBURG, PA.

FIBROID tumors of the uterus are benign even after cystic degeneration has occurred in them. The direct mortality from these tumors is, in my belief, greater than it was thought to be by the authors who wrote concerning them ten years ago. Many hitherto published statements emanating from operators became axioms, and, to some degree, impediments to surgical progress in the management of these tumors.

For instance, we were taught that unless the tumor threatened the life of the patient, we should not interfere with it. We were also taught that if the patient could be carried along until the menopause was established, that the tumor would gradually atrophy, and finally disappear. Further, we were taught that subserous fibroids did not require surgical operation. Finally, supra-vaginal hysterectomy was denounced as an unwarrantable procedure on any patient, unless without it her death was practically an assured fact. These teachings are rapidly becoming ancient history despite the desperate efforts and exaggerated statements of the advocates of electricity as a curative agent. In regard to the latter, men who did not own a battery, and who had never seen a fibroid tumor removed by an electrical current, have written elaborate articles on the subject. Happily for the surgeons, who had about arrived at a consensus of opinion in the surgical methods in the treatment of these cases, these "lightning bugs" have become in recent months less numerous. The dogmatical teachings, already referred to, are also being greatly modified and liberalized.

For the sake of brevity, let me say that in all fibroid tumors which have undergone cystic degeneration the propriety of their total removal with or without the uterus is a conclusion concerning which there is no debate. The non-cystic class, when projecting into the uterus, can be, as a rule, safely removed *per vaginam*, even when as large as an adult head. Such a case I reported some years ago, and the subject of the operation is still living and in good health. But it is only when such large tumors press upon and distend the cervix that their removal *per vaginam* is preferable to removal of the ovaries, or to supra-vaginal hysterectomy.

On the other haud, enucleation of submucous fibroids should not be undertaken, if it is reasonably certain that other small fibroids exist in the body of the uterus or project upon its serous surface. In such cases the removal of the ovaries is decidedly preferable; and this rule of action may safely apply to all fibroid tumors which are of the multiple or of the hard variety, and also to the softer variety prior to the time at which they have reached a size when hysterectomy, by reason of an available pedicle, might be done with a fair chance of success.

This brings us, then, to a consideration of those cases which are subserous in their relations. These tumors, when pediculated, should be removed by abdominal section. This opinion is based upon the observation of a number of pediculated fibroid tumors which persisted for many years after the establishment of the menopause; also upon the fact that they produce grave and troublesome symptoms leading to confirmed invalidism, and, in case of pregnancy, frequently endanger the life of the mother.

As will be seen, hysterectomy is left, therefore, for exceptional circumstances, such as when the condition endangers the life of the patient, and after

[1] Read before the Mississippi Valley Medical Association, 1890.

removal of the ovaries has failed, or until such measures appear useless from the start. Doubtless, hysterectomy is a grave procedure, and only justifiable when other means are of no avail. But to permit a woman to go from bad to worse until her vital forces are so exhausted that she will probably succumb to any surgical procedure, and then do upon her a supra-vaginal hysterectomy, is to subject the operation to an unwarranted test, and the surgeon to a foolish disregard of his own reputation. It is the old story of neglected opportunities for both patient and surgeon.

As to methods of hysterectomy, the extra-peritoneal plan of treating the pedicle is at present the best. Even when the pedicle is short, it may be lengthened by having first secured the cervix at the vaginal junction with an elastic ligature, bisecting the uterus, shelling out the tumor, and permanently securing the now lengthened cervix at a higher point; or, having separated the uterus by division of the broad ligaments between properly-applied ligatures on the outer side, and having clamped forceps on the uterine side, the object will be attained; or, separation of the bladder from the supra-vaginal cervix, and enucleation of the tumor prior to amputation of the body of the uterus, may result in a good pedicle. Finally, it may be advisable to take out the neck entirely, as has been repeatedly done successfully, notably by A. Martin, of Berlin, and Eastman, of Indianapolis.

The question of constriction of the pedicle is one of importance. For this purpose malleable iron wire has given excellent results; it has the disadvantage, however, of requiring a careful watch during the first seventy-two hours. The fact that elastic tubing used as a ligature takes care of itself, renders it safer than the wire; but, in my experience, the slough dips deeper into the cervix than when the wire is used. The best outer-dressing of the pedicle has been debated. Bantock simply packs the pedicle in dry thymol gauze. Tait, Keith, and others mummify it, some with the cautery, others with the perchloride of iron. After trying various methods, that which has given the greatest satisfaction is the following: After the abdominal wound is closed, the stump is hollowed out and trimmed down inside of its peritoneal covering as far as is safe, and a large quantity of subsulphate of iron (Fenton) is placed upon it. The peritoneal covering of the stump is "whip-stitched" across this as much as possible, a large piece of sheet rubber having first been securely placed below the pins and drawn firmly against the pedicle.

The space between the upper margin of the knob of the pedicle and the pins is carefully packed with gauze; over this packing and over the top of the pedicle the subsulphate of iron is freely sprinkled—in fact, the pedicle is thoroughly covered. A handful of gauze is then placed on the top of all this, the sides of the "rubber dam" are brought up over all, and the binder applied. A pedicle thus dressed emits no odor whatever, and requires no looking after until it drops off.

In a case recently treated by this method in my Sanitorium the temperature never passed the physiological limit (99.5° F.), the patient's pulse remained correspondingly good throughout, and she required no attenton beyond that given by the nurse.

Hysterectomy is an operation not to be lightly undertaken; although I had witnessed many cases among European surgeons during 1881, 1882, and 1883, it was not until after I had done a hundred abdominal sections that I felt entirely comfortable concerning an approaching hysterectomy. But the operation, in the hands of surgeons of experience and under proper surroundings, will improve in statistics and establish itself upon a sound basis.

DISCUSSION.

In discussion DR. L. S. MCMURTRY, of Louisville, said that, in considering this subject, it is necessary at the outset to recognize the fact that fibroid growths are of two distinct kinds—the multiple, nodular fibroids, and the large, soft, œdematous fibroids. These two classes are distinct pathologically and clinically, and require different methods of treatment. The multiple, nodular fibroid is a tumor which produces, as a rule, no serious troubles, and frequently disappears at the menopause. A simple exploratory incision into the abdomen has often been followed by disappearance of these tumors. When their growth is active, pressing upon adjacent organs, accompanied by menorrhagia, and exhausting the patient by loss of blood, the operation of removal of the uterine appendages is one of the most prompt in relief and satisfactory in results of the many brilliant operations known to modern pelvic surgery. The hæmorrhage is arrested, the tumors shrivel, and the patient is restored to health. The mortality of this operation in skilled hands is less than two and one-half per cent.

With the soft, œdematous fibroid or uterine myoma it is altogether different. These tumors may appear either early or late in life. The speaker removed one which occupied the abdominal cavity up to the epigastrium in a woman more than fifty years of age, while Dr. Sutton has the specimen of one removed from a girl of sixteen years. These tumors are not arrested in their growth by the menopause. They increase with rapidity; they press upon the bladder, kidneys, intestines, stomach, and the great bloodvessels; they excite frequent attacks of peritonitis; the patient is exhausted by pressure-symptoms; her feet and limbs swell, and emaciation and death follow after months of increasing suffering. The growths undergo cystic degeneration and in some instances they break down in places, forming suppurating cavities in the mass.

The only treatment for this latter class of uterine tumors is complete excision by supra-vaginal hysterectomy. In many instances the mushy, œdematous fibroids,

particularly if cystic degeneration has taken place, cannot be diagnosed from ovarian cystomata. The first supra-vaginal hysterectomy that the speaker performed he thought, before opening the abdomen, would be an ovariotomy. Operators of the widest experience and most acute diagnostic skill have had the same experience. Indeed, he said, it is not easy, even *after the peritoneum has been entered*, to distinguish a soft uterine myoma from an ovarian cyst. Both tumors are of a pearly hue, and both fluctuate. For this reason the operator who undertakes ovariotomy should be fully prepared to do supra-vaginal hysterectomy.

Of late, electricity has been much vaunted in the treatment of fibroid tumors of the uterus. Dr. Sutton merely mentioned this agent in his paper, probably purposely, because he knows that electricity does nothing toward arresting or removing these tumors. A peculiar feature about the application of electricity in pelvic surgery is, that those who a few years since denied the existence of certain forms of intra-pelvic disease are now foremost in the diagnosis and treatment of these same diseases by electricity. The application of electricity by puncture is fraught with great danger. The speaker has removed a uterine myoma by supra-vaginal hysterectomy, weighing sixteen and a half pounds, in which the entire anterior aspect which had been accessible to electric treatment was bound by dense adhesions to the omentum, intestines, and abdominal wall. It is because abdominal surgeons have the opportunity to see the results of electrical treatment that they are so universally opposed to its use. Much has been said of Thomas Keith's advocacy of the treatment of fibroid tumors of the uterus by electricity, but in a recent public utterance in this country, Dr. Keith's son announced that it is altogether a mistake that his father has abandoned hysterectomy, adding that he had just received a letter stating that his father had recently done a hysterectomy. This is a significant announcement at this time.

The important fact to grasp is that these tumors destroy life and that the operation for their removal is done to save life. The results of supra-vaginal hysterectomy, with extra-peritoneal treatment of the pedicle, in skilled hands are so excellent that the method is deserving of increasing confidence and wider application. It is not just to patients afflicted with uterine myomata to assure them that these tumors are unimportant, will do no harm, and disappear after the change of life. Operation should be recommended before adhesions have formed and before the patient becomes emaciated and exhausted.

DR. C. H. HUGHES, of St. Louis, said that he would refer to only one point in connection with the treatment of uterine fibroids, because these diseases were not in his line of practice. He has employed electricity therapeutically for twenty-five years, and for ten or fifteen years he has used it very extensively. In regard to the employment of the agent for the purpose of dispersing morbid growths, whenever a morbid growth has passed beyond the reach of the absorbent system and it is doubtful whether it can be influenced through the vasomotor mechanism that governs the arteriole circulation, then electricity is not likely to be of value. It is the empirical use of it, without due regard to its physiological impress upon the ganglionic centres and the circulation controlled by them, that is at fault. It is a misunderstanding of this fact which has caused much discrepancy of opinion in regard to the results of electrical treatment.

The subject of electrization in the control of intra-pelvic vascular conditions was studied long before Apostoli came upon the scene, and long before he stated that these conditions can be influenced through the vasomotor mechanism which controls the pelvic arteriole circulation, by galvanization. It will do in hyperæmia connected with the intra-pelvic viscera, just as in cases of cerebral hyperæmia, and those who have tried it as a therapeutic measure know that the effect is the same upon the viscera of the pelvic and abdominal cavity as it is on the cerebrum. Electrization, from the speaker's experience, applied to intra-uterine fibroids and other tumors of the pelvic viscera, is a valuable therapeutic measure.

In the early treatment of developing tumors of the pelvic or other viscera it ought, in every instance, to anticipate the knife; but in the later and final stages of many morbid growths it will not supplant surgical interference.

The true test of its value is in its control of conditions which promote the growth of tumors and in arresting their progress, while, at the same time, it improves the general tone of the patient and makes him or her more resistive to the local disease.

DR. RUFUS B. HALL, of Cincinnati, said that, although a number of surgeons claim that the intra-peritoneal method is safer than the extra-peritoneal method in supra-vaginal hysterectomy, yet with Dr. Price's record of thirty-one consecutive recoveries after operations, and the good results obtained by other operators, which prove it to be the best method yet devised, we have no reason to abandon it for the intra-peritoneal method. We know the peculiar nature of the tissue with which we have to deal, and the only safe method of controlling hæmorrhage is to have the wire external, so that it is under control. When the stitches are inserted in the abdominal wound the wire can be twisted with the serre-nœud as tight as before placing the stitches, but before closing the wound the wire will be quite loose, so rapidly does the stump shrink, and the serre-nœud will require two or three half-turns. This shrinkage goes on for a number of hours.

The speaker could not understand why Dr. Sutton recommended mutilating the tumor instead of making a long incision. He has seen tumors weighing as much as forty-nine pounds removed by supra-vaginal hysterectomy, and the wound heal as well as if the incision was four inches long. Many of the complications which occur from the effort of trying to remove a long fibroid through too short an incision, would not take place if a long incision was made. He is in favor of making an incision long enough to permit turning the whole tumor out at once, and which will not require removing the tumor in pieces, which is a very unsurgical procedure.

The question of making a pedicle is one that is exceedingly interesting to the operator, and of vital importance to the patient, and he regretted that Dr. Sutton had not seen fit to elaborate that very interesting point.

The speaker recently operated on two cases, in both of which, when the tumors were first turned out, the pedi-

cles were as thick as a man's thigh. These are the cases that try the operator's skill and patience. Of course, we can make a pedicle, but we do it with more or less difficulty, and the tension afterward is very great, and complicates and retards the convalescence.

DR. C. A. L. REED, of Cincinnati, thought that one of the most important points in the paper of Dr. Sutton was the reference to the common practice of advising non-interference when patients are approaching the menopause. The fact has been emphasized by Dr. McMurtry that the majority of fibroid tumors of the uterus do not disappear at the menopause. The statement was made by Keith, and has been repeated in many of the text-books, that they atrophy and disappear with the onset of the senile changes which begin at the change of life. The speaker recently saw a case under the care of Dr. Joseph Price in Philadelphia, of a woman who developed a soft myomatous tumor at the age of fifty-seven years. This tumor developed twelve years after the menopause had occurred, and an operation was done to arrest hæmorrhage.

A single case, such as this, and he thought there were others, completely upsets the theory which is based upon purely negative observations. He believes that many tumors with hæmorrhagic characteristics, that develop in elderly women, and which we are disposed to look upon as malignant, are undoubtedly cases of soft myomata; and with the demonstrated low mortality which follows the perfected operation of supra-vaginal hysterectomy, many cases might be subjected to operation which are allowed to go on without operative interference, only to die from a slow process of exsanguination.

NEW PROBLEMS OF NUTRITION IN HEALTH AND DISEASE.[1]

BY A. B. MACALLUM, B.A., M.B., PH.D.,
LECTURER ON PHYSIOLOGY IN THE UNIVERSITY OF TORONTO.

(Concluded from page 186)

From all the facts in the preceding part of this paper the inference is to be drawn that chromatin contains iron as an integral part of itself. I resolved, if possible, to put this inference to the test of actual demonstration, but owing to the pressure of other work no opportunity presented itself till this autumn, when Mr. R. R. Bensley, working in the Physiological Laboratory of the University of Toronto, kindly undertook, at my request, the investigation. After fruitless attempts to demonstrate micro-chemically the presence of iron in the large nuclei of the salivary tubules of insect larvæ, it occurred to us to isolate large quantities of chromatin from the organs not concerned in blood-formation, as the liver is supposed to be in higher animals. For this purpose lambs' testicles were minced up, the cellular elements extracted with water containing 0.2 per cent. of hydrochloric acid, digested with pepsin and hydrochloric acid for several days until the clear fluid gave no peptone reaction, and the residue extracted first with alcohol, then with ether to remove fats and even the slightest trace of hæmatin. The chromatin so prepared gave no iron reaction in the cold with ammonium sulphide or with solutions of potassic ferrocyanide, but when ashed, and the ash extracted with weak hydrochloric acid, the extract gave marked iron reactions with ammonium sulphide, potassic ferrocyanide and ammonic sulphocyanide. These experiments were tried over and over again with the same result, and a number of control-experiments were also carried out to prevent mistake or error.

The iron in the chromatin cannot be detected by any of the ordinary chemical tests, and, therefore, is analogous to Zaleski's *hepatin*. It is only when the chromatin is heated with ammonium sulphide that any reaction occurs, and even then it is feeble, whereas with the hæmatogen of egg-yolk it takes place much more readily and distinctly.

Mr. Bensley has also prepared small quantities of chromatin from the thymus of the calf, and has found that it too contains iron as firmly combined as is that of the testicle.

I think that it is now definitely determined that *the nucleus of every living animal cell contains an iron-holding proteid, and that this compound is the one which is regarded by cytologists as the controlling factor in the life of the cell.* I propose to keep the name chromatin[1] for this compound and leave the term nuclein for a derivative of it.

It may be asked how it was that the earlier students of the nucleins overlooked the presence of iron. They usually separated the nucleins by peptic digestion, then dissolving the residues, and washed with ether and alcohol, in solutions of caustic soda, precipitating them therefrom with hydrochloric acid, redissolving and reprecipitating several times. The precipitate so obtained, the so-called soluble nuclein, cannot, after such a thorough course of treatment, be held to represent the original chromatin. The nucleins which the earlier chemists isolated from the egg-yolk were put through this vigorous method of preparation, and it is not surprising that the observers did not detect the iron in them which Bunge found to be present only a third less abundantly than in hæmoglobin of mammalian blood, and little less so than in the hæmoglobin of chicks. *A priori*, we should expect that the ground-substance of life has a more complicated constitution, a larger number of atoms of each of the single chemical elements present in it, than albumin or globulin. Yet chemists have approximately determined the formula of nuclein as $C_{29}H_{49}N_9P_3O_{22}$, while Zinoffski[2] has given good

[1] Delivered as one of the lectures of the Post-graduate Medical Course of the University of Toronto, December 20, 1890.

[1] The fact that chromatin gives origin to hæmoglobin and probably also to nuclein, renders the name very appropriate.

[2] Ueber die Grösse des Hæmoglobin Moleküls. Zeit. für Physiol. Chemie, Bd. x. p. 16.

reasons for believing that the molecule of albumin or globulin contains more than thirteen hundred atoms of carbon with the atoms of the other elements present in it, correspondingly numerous.

As I have already indicated, hæmoglobin[1] is derived from the chromatin of the hæmatoblast. Now, the formula of the hæmoglobin molecule is, according to Preyer, $C_{600}H_{960}N_{154}FeS_3O_{179}$, or, according to Zinoffski, $C_{712}H_{1130}N_{214}S_2FeO_{245}$. Can we conceive then of a nuclein, if it be like chromatin, and with a formula of $C_{29}H_{49}N_9P_3O_{22}$, giving rise by degeneration or otherwise to a compound of the formula $C_{600}H_{960}N_{154}FeS_3O_{179}$? If so, then a compound by degeneration or otherwise gives rise to one in which the atoms are more numerous, the oxygen relatively less abundant in volume and, therefore, the chemical energy greater. To take this position is to overthrow all our ideas of assimilation. Is it not simpler to assume, as Bunge has done in the case of hæmatogen, that only vegetable cells can, under the influence of sunlight, store up energy in the form of complicated compounds, of which the chromatins are examples, compounds which when transferred to the animal cell undergo transformations and present phenomena which are grouped under the term vital?

In the hepatin of Zaleski and in the chromatin of the testicle and thymus, the iron is as firmly combined as it is in hæmatin or in hæmoglobin. Such a firm combination means the storage of energy. Can we believe that the animal cell is capable of such a storage? The animal cell cannot build up albumins out of any simpler substances.[2] It is evident that the chromatins are more complicated than the albumins. It is reasonable on this ground alone to conclude that the chromatins are derivable from the vegetable cell more or less directly. This explains why such care is taken by nature to provide the embryo with a supply of chromatin which will suffice until it reaches that stage of existence when it can maintain the supply from its food. In the placentæ of cats, which I studied, I found that the endothelial cells of the maternal bloodvessels were hypertrophied, that these eventually disintegrated, and that their chromatin was swallowed bodily by the covering cells of the fœtal villi. I found, further, that in the glands at the base of the mucosa the epithelial cells proliferate and finally disintegrate, and their chromatin is cast only into the lumen of the gland. Where the fœtal villi break through the walls of these glands the fœtal epithelial cells, amœboid in outline, absorb these chromatin masses and granules. There are also, especially in some of my preparations of the placentæ at a certain stage, solid columns of chromatin in the ovial portions of the villi. At a later stage these chromatin masses are smaller and seem slightly changed in chemical composition and are like mucin in some respects. I found also *that amœboid cells were engaged in transferring the chromatin from the neighborhood of the epithelial cells of the villi and from the ovial portions of the villi to the blood-channels.* The chromatin so transferred from the maternal to the fœtal tissues is evidently the vehicle for the iron which the embryo receives and which, as shown by Bunge, is much greater in amount per kilogramme of body-weight in the newborn than in the older or adult animal.

This brings me to one of the problems of this paper. If chromatin is, as I have said, derived as such, either remotely or directly, from the vegetable kingdom, how is it taken into the system? I may say that this is one of the problems which I propose to study in the next few months. Without prejudging the question, it is possible to touch on some of the aspects of it which raise other problems for solution. As I have intimated, amœboid cells in the fœtal villi are concerned in the transference. We may infer from this that the amœboid cells of the adult, the leucocytes, play an important part as chromatin-carriers. As the covering cells of the fœtal villi are from their shape engaged in the absorption of chromatin, it is possible also that the intestinal epithelium of the adult individual is capable of absorbing very small particles of chromatin. It may be that the leucocytes which, as Stöhr and others have shown, wander out into the intestinal cavity or to the free surfaces of the epithelial cells, take up from the chyle particles of chromatin.

If the leucocytes are the principal agents in the absorption of chromatin, we may explain the existence of hæmatoblasts and the formation of hæmoglobin. For in *amblystoma* larvæ at an early stage the first blood-corpuscles are *amœboid;* they wander about in the tissues and especially among the yolk-cells, and they in consequence are capable of obtaining a greater quantity of yolk-spherules than the fixed cells. These yolk-spherules contain the hæmatogen of Bunge and, therefore, the corpuscles have a greater supply of chromatin, which is utilized in the repeated and rapid divisions of the hæmatoblasts. This greater abundance of chromatin in the hæmatoblasts has been noticed by Flemming, Pfitzner, and Peremeschko. Obviously, with a greater quantity of chromatin than the dividing cell usually has, some of it is useless as such, degenerates and appears as hæmoglobin. Such,

[1] The pigment of muscle-fibre, the myohæmatin of MacMunn, the hæmoglobin of Levy and Hoppe-Seyler, in *amblystoma* larvæ, is apparently derived *directly* from the hæmatogen.

[2] Apparently the animal cell is capable of converting simple compounds into more complicated ones by the process of hydrolysis only, as, for example, peptones in albumins.

amœboid corpuscles are most abundant in the neighborhood of the yolk, and they are collected in large numbers at a certain stage in the smaller vessels connected with and lying on the yolk-holding organ. The blood-current in these vessels being slow the hæmatoblasts are then delayed where they divide and redivide, and eventually are converted into fully-formed red corpuscles. After a certain stage only one of these collections usually persists. This becomes the spleen, which *is thus developed in intimate relation with the hæmatogen-holding organ. When the yolk is nearly absorbed, the leucocytes make their appearance as such;* but I maintain that the first blood-corpuscles of the embryo are leucocytes, or amœboid cells of the same nature and origin as leucocytes, but become hæmatoblasts because they have absorbed or taken up an excess of chromatin from the yolk. In like manner we may account for the apparent absence of leucocytes from the mammalian embryo up to a certain stage of its history. The first blood-cells are really leucocytes, but as their principal function is to carry chromatin from the villi to the embryonic organs, they are loaded with an excess of chromatin, a part of which, on the *lunus-consumption* principle, they probably convert into hæmoglobin. From the absence of leucocytes during the first six weeks of human embryonic life it might be reasonably inferred that the greater part of the chromatin which the embryo receives is obtained during those six weeks.

In adult mammalia the whole or the greater part of the chromatin of the hæmatoblast is converted into hæmoglobin, and as a result the chromatin-holding organ, the nucleus, is no longer necessary, hence it degenerates and disintegrates, as Osler believes, or is extruded from the cell, as Rindfleisch and Howell maintain.

The animal body is very saving of its chromatin. I found this well illustrated in my studies on the pancreas and intestinal epithelium of amphibia.[1] When a cell disintegrated the débris became swallowed by the immediately adjacent cells, the cell-protoplasm of the swallowed particles speedily dissolved, leaving the chromatin alone in cavities of the cell. Secretion on the part of the containing cell continued, but *the nuclei enlarged as a result of the solution of chromatin in the cell, frequently to twice its original size. The amount of chromatin in such enlarged nuclei is greatly increased.*

Now I come to a brief consideration of what I call the storehouses of chromatin. By this I mean that the giant cells in the bone medulla of higher animals and in the spleen of some mammalia. I cannot enter into the reasons here in this already long article why I so consider them. It is sufficient to say that these giant cells store up the more or less changed chromatin, so that it can become available to the immediately adjacent hæmatoblasts, or, to speak more correctly, marrow cells. There are also giant cells in pathological growths, for example, myeloid sarcoma and tubercle. In the former the chromatin is derived primarily from the numerous disintegrated and often from swallowed leucocytes. I believe from my observations, that in tubercle the giant cell is derived in the following way: The epithelioid cells are injuriously affected by the ferment or more probably albumimose secreted or produced by the tubercle bacillus, and also by the lack of such nourishment as a proper blood-supply brings. As a result of this the cells degenerate, disintegrate, and their chromatin is set free. One or more of the surviving cells at the periphery of the tubercle immediately absorb or swallow the free particles of chromatin, and as a consequence nuclei of such cells have to multiply perhaps a hundred times to accommodate the increased supply. With such a supply of chromatin it is not surprising that such cells can withstand their unfavorable environment. Indeed, I believe that the absence of bacilli in many of such giant cells is to be explained on the supposition that they throw out or secrete from their nuclei a compound, albumose or other material, which overwhelms the bacilli. Could we artificially produce that compound we would have a therapeutic agent which would rival all others brought forward since the history of medicine began. I have indicated in one of my papers[1] facts which show that the pancreatic ferment arises from the chromatin of the pancreatic nuclei as a *prozymogen* compound which is deposited in the cell protoplasm, and probably united with an element of the latter as zymogen, and as this gives ferments which are now regarded as albumoses, we may readily believe that Hankin's defensive albumoses are derived from the chromatin of the cells of the system.

As the vitality of the cells and, therefore, of the adult individual depends on the amount of chromatin, we can possibly account for the absence or the presence of the quality of immunity to diseases. Can it be that the individual readily disposed hereditarily to contract, say tuberculosis, has received less than the proportionate amount of chromatin in embryonic life? Has the vigorous individual at such a period received an abundant supply of chromatin? We know that iron is beneficially administered in wasting diseases and often in tuberculosis. Is the explanation of its action that of a tonic or so-called hæmatinic?

[1] Results of these studies are to appear in a forthcoming number of the Transactions of the Canadian Institute.

[1] In a forthcoming number of the Transactions of the Canadian Institute.

Rather, I believe, that it protects the iron-holding proteids of the food in the intestinal canal from decomposition, and thereby permits a larger quantity of such proteids to be absorbed to increase the chromatin of the system and therefore its vitality? Is it possible to increase the amount of chromatin in the system by any other process than intestinal absorption? Bearing in mind the fact that in the cat's placenta chromatin is transferred from the maternal to the fœtal tissues under conditions which constitute complete asepsis, it is possible that a similar endowment of the adult system with chromatin may be brought about by hypodermic injection under aseptic and antiseptic conditions. I think that in the future the latter may be found quite feasible. Indeed, I believe it has already been done by Brown-Séquard, with extracts of the fresh testicle, and that this transferrence, hypodermically, is the cause of the beneficial results so obtained.

The reader will observe what a large number of questions are connected with the absorption of chromatins. It is not possible to formulate in this article all the aspects of the relation of chromatin to nutrition, and I will merely touch briefly on some of the clinical considerations which present themselves in my mind.

Simple anæmia and chlorosis are usually held to be diseases in which the blood-formation is diminished, and which is caused by the lessened absorption of iron salts from the food. Bunge believes that they are caused by a lessened absorption of the hæmatogens of the food, and that this lessened absorption is brought about by decomposition in the intestine of hæmatogens through alkaline sulphides. Anæmia and chlorosis in either case are caused by a lessened resorption of those materials which go to form hæmoglobin. Now I maintain that *both diseases are primarily due to a lessened absorption of chromatins from the food, and that the diminished hæmoglobin formation is merely symptomatic of this condition and does not constitute the primary trouble.* Every cell in the body suffers from want of chromatin, and, as there is a lessened supply of chromatin, less can go to the formation of hæmoglobin. With the lessened supply of chromatin the tissues cannot grow to their usual volume through cell-division, and, therefore, we find in the bodies of chlorotic patients, who come to a post-mortem examination, that condition which Virchow describes as *hypoplasia*, and which he apparently believes to be the cause, in some cases, of chlorosis. In these cases the organs, notably the aorta and large arteries, are of narrow calibre, they are not as fully developed as one would expect in such individuals. No doubt the lessened calibre of the great vessels diminishes—through the increased resistance they offer—the effective power of the heart in driving the blood to the various organs, and thereby diminishes also the nutrition of the various parts, but this I think is a secondary trouble, the primary one being the lessened absorption of chromatins and the thereby lessened proliferation of the tissues in the various organs, the aorta and other bloodvessels amongst these.

Bunge, in one of his papers, hints at the hypothesis that, in young girls at puberty, there is a storage of hæmatogens in some organ which are to be transferred to the developing ova when impregnation takes place, and that at puberty in chlorotically inclined patients this organ makes a demand on the hæmatogens of the body, which would otherwise go to blood-formation. There is some truth in this view. At the commencement of puberty the ovaries and the uterus enlarge, and the uterine mucosa consequently undergoes an increase in volume; this means, of course, an increased supply of chromatin, and if the system is deficient in this substance chlorosis results. Why should there be a deficiency of chromatin in the body of such individuals? I may say that probably intestinal decomposition of the food-chromatins before puberty might bring about such a diminished supply in the body, but I think I can better answer such a question by asking another: Are there any great variations in the quantity of chromatin which is transferred from mother to child through the placenta? If, as I maintain, the digestive ferments arise from the chromatin of the cells of the digestive organs, any lessening of the usual amount transferred to the child through the placenta must lessen the amount of the digestive ferments secreted in the adolescent body, and, as the supply of chromatin given through the placenta cannot be made up by intestinal absorption, because of the diminished digestive function, the adolescent female reaches the period at which puberty begins with a seriously diminished supply of chromatin, and chlorosis, probably in many cases with hypoplasia, is the result.

As already intimated, the greater part of the chromatin is probably transferred, during the first six weeks of pregnancy, from the mother to the fœtus. Are the nausea and vomiting of pregnancy caused by such a transferrence with a consequently diminished secretion of digestive ferments and lessened digestive vigor? At any rate, the anæmia during and following pregnancy is easily explained, as will be understood from what I have said, by this transferrence.

Under the so-called pernicious anæmia we apparently group a number of conditions. Some of these I shall treat of again, but at present will refer to one or two forms of this disease. It has been found, on post-mortem examination, that the gas-

tric mucosa is atrophied. In such cases it is evident that the food is only half digested, and, therefore, only half the chromatins are set free from the other proteids, and that only half the usual amount of chromatin is absorbed. Further, the pancreatic ferments are also probably thereby lessened, and less still of chromatin isolated and absorbed. With atrophy of the gastric mucosa the putrefactive germs gain free entrance, putrefaction in the intestine is enhanced, and it is not surprising that the result is fatal. In some cases of pernicious anæmia, no doubt, there is hæmolysis as Hunter has, I believe, shown, and Mott ascribes this hæmolytic function to an albumose produced in the intestine and absorbed into the bloodvessels. Such cases more truly constitute blood-diseases than simple anæmia and chlorosis do. We may suppose in such cases of albumose-absorption that the food-chromatins are decomposed by the germs which are the agents in the production of the albumose.

Once again, if the leucocytes are the active agents in the absorption of chromatins from the food, is splenic leukæmia due to an over-resorption of food chromatins?

I have put many of the problems arising out of the relation of the chromatins to nutrition in the form of questions. I hope they will stimulate others to seek for solutions to them, as I have been stimulated to work up the basis on which these problems rest. I may be pardoned for believing in the importance of these problems, for who could think and work for four years on subjects such as I have here treated of without considering them to be of great value. I may also say that I think more attention ought to be paid to the physiology of cells than is done even at the present day. Cytologists have been principally engaged on the structure of the cell, because results are more easily won in that line. From what is here said I hope more attention will be directed to the great value of the study of the seemingly hidden processes which are grouped under the name of cell-physiology. If we could particularize as to what changes other than structural occur in the cell, we *might* generalize about the colony or the mass of cells, or the individual formed out of them. In that case also we probably could do in the way of therapeutical treatment what we think fanciful and extravagant now. In any case I hope I have thrown a little light on a dark road, along which we may travel there is no knowing how far. It will be seen in the several papers which I shall publish upon the subjects touched on here on what evidence my views rest.

CLINICAL MEMORANDUM.

PÆDIATRIC.

The Treatment of Convulsions in Children.—In a case of convulsions in a child, if the patient is cyanotic, a few whiffs of amyl nitrite, followed by inhalations of chloroform to relax spasm, should be given. These should be followed as soon as possible by hypodermic injection of tincture of veratrum viride, one-half drop for each year of age up to six years. The veratrum may be repeated in half an hour or an hour if the convulsions recur. If the convulsions are uræmic, a small dose of morphine may be added or given separately.

In all the cases in which I have employed the foregoing treatment the effect was remarkably good, and in but one case have I had to repeat the injection of veratrum. The convulsions cease, the muscles relax, the pulse becomes slower, the temperature falls, and the skin becomes moist.

Indeed, the danger is over in less time than by any other means I have seen employed.

Appropriate after-treatment, as may be indicated, should of course be adopted.

Theodore G. Davis, M.D.

ORIGINAL LECTURES.

PLEURITIC EFFUSION—SOME PECULIARITIES OF TYPHOID PNEUMONIA—THE TREATMENT OF CONSUMPTION BY KOCH'S LYMPH.

A Clinical Lecture
delivered at the Pennsylvania Hospital.

By J. M. DA COSTA, M.D., LL.D.
of Philadelphia.

Case I.—Gentlemen: I thought you would still be interested in this case of effusion into the chest that was before you on another occasion. The man has been doing remarkably well, and we have had no occasion to change the treatment that was ordered when you last saw him. You remember that at that time he was placed upon 20 grains of acetate of potassium, 15 drops of the tincture of the chloride of iron, and 5 drops of dilute acetic acid in syrup of lemon and water every fourth hour. The affected side was painted with tincture of iodine, his diet was restricted almost exclusively to solid food, and, in addition, two or three times a week he had a saline laxative consisting of two drachms of sulphate of magnesium, which was sufficient to produce free action from the bowels. Under this treatment we have had excellent results. His heart which, as you may remember, was displaced, is now in its natural position; you will recall the dulness on the right side, which does not begin until the midsternum is reached, indeed, a little to the left of midsternum. The region over the lungs shows no dulness until we reach the sixth rib, and at the upper part of the chest, both anteriorly and posteriorly, we have vesicular breathing. About the fourth rib anteriorly a friction-sound is perceived, but the vesicular breath-sounds can be heard even low down in the chest posteriorly until we come to the very lowest limits, where they are still feeble. The vocal vibrations

are also heard naturally until quite low in the chest; the fremitus is not, however, perceived below the angle of the scapula, it has not improved in proportion to the other physical signs, but, considering the whole result, it may be said that the effusion has almost disappeared. Under these circumstances we can do nothing better than to continue this treatment. I believe complete recovery will soon take place.

TYPHOID PNEUMONIA, WITH OBSERVATIONS ON ITS TEMPERATURE-RECORD.

I had ready for you two cases of typhoid pneumonia, but I shall have to limit myself to exhibiting one case only, because in the second case, while he is doing well enough as regards the typhoid pneumonia, a complication has developed in the shape of a swelling of the glands of the neck which makes it too great a risk to move him from the ward. I will show you this case, however, which is a very typical one. He was admitted on December 29th, and at that time had had fever and cough for three days. The sputum was admixed with blood, he had a pulse of 120, respirations of 36, and a temperature of 103°, which soon rose to 104°. There was impaired resonance at the upper part of the left lung anteriorly. Anteriorly the right, from the clavicle down to the fourth rib, was dull on percussion, and posteriorly it was dull throughout. There was also slightly-impaired resonance at the lower part of the left lung. The breath-sounds on the left side were harsh and accompanied by crackling râles at the upper part. On the right side anteriorly there existed bronchial breathing down to the fourth rib, and posteriorly an occasional moist râle. There was, therefore, lobar pneumonia of the right lung, except at the lower part anteriorly. On the left side there was also bronchial catarrh as a complication and some consolidation at the apex, so that, in some respects, we might have called this a case of double pneumonia.

There were other points of interest in the case. The man presented a dry, cracked tongue like that of typhoid fever, a pulse of 120, which, however, after a day or two declined to 108. The pulse was very fluctuating, occasionally reaching 124. The respirations varied between 36 and 54; the sputum remained rusty, great exhaustion manifested itself, and, in truth, what might be called a typhoid condition became so marked that we entertained, though we set it aside, the possibility of the case being one of typhoid fever with a lung complication. The man's nervous phenomena were those of wild delirium, and so wild was the delirium that he had to be strapped. While, then, the signs of the disordered nervous system, the dry tongue, the frequent pulse, the evident exhaustion, the sweating, all pointed to a typhoid state, the bowels remained in their natural condition—about one movement daily. The passages were not liquid except on one day, when there were several. He never had an eruption. The case was so strikingly like one of typhoid fever that we had our minds on that possibility for some days. Now, however, it is proved that the first impression was correct, it was simply a case of typhoid pneumonia with grave symptoms referable to the nervous system and with the signs of marked prostration.

This morning you see him in a very much better condition than when he came into the hospital. His tongue is becoming moist, the delirium ceased three days ago; his pulse this morning is only 60; his respirations are 22, and his temperature 97⅘°, the highest temperature being 104⅗°, so that you see before you, certainly as regards his rational symptoms, a convalescent.

Now let us see how these symptoms correspond to the physical signs. You may recollect that we had some dulness of the left apex; that is now gone, the percussion resonance there being clear. On auscultation there is simply slightly harsh vesicular breathing. The area of consolidation has therefore gone. On the right side, where marked disease existed, we have now clearness on percussion anteriorly and, what is very interesting, under the right clavicle, the middle of the right lung, the sound has a slight tympanitic admixture, a condition of things to which I called your attention in a previous case. On auscultation anteriorly we have harsh but vesicular breathing, mixed with a few, rather coarse, moist râles, so that it is evident that almost complete resolution has taken place. When I tell the patient to get up he does so with difficulty, and on auscultating the back I find that the bronchial sounds have disappeared, but there is some harsh respiration, with rather marked expiration near the angle of the scapula; the breathing is everywhere vesicular, however, with a few coarse râles. Therefore, practically, the pneumonia is over. This is a very gratifying result, if you remember how very ill this man was.

Before I take up the subject of his therapeutics, I will say that the urine was examined throughout and showed no albumin. I wish also to call your attention to the temperature-chart, which is very interesting. You see here the elevations of temperature. I will not go into details, but they range between 103° and 104°; after reaching 104° there are slight variations, and then a rise to 103½° until the 27th; and from that time on, with slight rises, the temperature gradually, but uninterruptedly, fell, so that this case of typhoid pneumonia has convalesced as many cases of ordinary pneumonia do, by what you might call a crisis. The temperature-chart is singularly interesting from this point of view. If we had had any doubt that this case was one of typhoid fever with lung complication, on account of the gravity of the other symptoms and the typhoid condition which appeared to be present, this temperature-chart would be most significant. This leads me to remark that the diagnosis between typhoid fever and typhoid pneumonia is often an extremely difficult one on account of the symptoms called, for convenience' sake, typhoid, namely, impairment of the nervous system, dry tongue, signs of exhaustion, and the like; but what you do not have are the characteristic temperatures of typhoid fever. Again, you do not find, or certainly very rarely, in typhoid pneumonia a sustained temperature; in other words, you will have the ordinary temperature of pneumonia—the time will come when the temperature drops so rapidly that you will have something approaching to a crisis, without the rises and falls found in the beginning of convalescence from typhoid fever. Further let me say that while the temperature-curve in typhoid pneumonia is, in the main, similar to that of ordinary pneumonia, yet what is called the crisis, viz., the sudden cessation

of the fever, is more prolonged in typhoid pneumonia than it is in ordinary pneumonia. In the case before us this crisis has extended over four days, whereas in an ordinary case of pneumonia it would have taken place in twenty-four or, at the utmost, thirty-six hours.

Now that I have explained to you this case from a pathological and diagnostic point of view, let me make some remarks as to its treatment. When he was admitted he was given a fever mixture of citrate of potassium, together with carbonate of ammonium; he also had twelve grains of quinine daily. To this treatment turpentine was added on the 28th, ten drops every fourth hour. Occasionally we gave him hyoscine at night, in doses of $\frac{1}{120}$th of a grain, which quieted him, and gave him relief for two or three hours; especially quieting the delirium. This is an interesting example of the usefulness of hyoscine in acute diseases. On the first few days, half an ounce of whiskey was given him every fourth hour, but when the typhoid symptoms showed themselves we gave it to him every second hour. Of course, he was given nourishing food, milk, broth, and the like. For the rise of temperature, which exceeded 104° on one occasion, salicyl-bromanilin was given—the new compound of salicylic acid, bromine, and anilin, which is to take the place of phenacetin. The drug was given in doses of five grains, and the effect in this case was good. In these doses it at once reduced the temperature a degree and quieted the nervous system. We had previously given the patient phenacetin, so that the observation was an interesting one, and while we found, on comparing the effects of the two drugs in the same case, that phenacetin in small doses lowered the temperature more (even three grains had more effect than five grains of salicyl-bromanilin), yet as regards its influence in quieting the nervous system, in the procuring of sleep, in the lessening of delirium, and in the general effect on nervous tension, the new remedy proved the better.

It is instructive to study the delirium in this case, and to see how it was influenced by the different drugs and by stimulants. Remember that it was so violent that we had to restrain the man in bed by force. The greatest effect from any of the agents we used was from hyoscine. Atropine and morphine, which we employed on one or two occasions, had very little effect in doses of $\frac{1}{6}$th of a grain of morphine and $\frac{1}{120}$th of a grain of atropine. The stimulants neither increased nor diminished the delirium. Next to hyoscine, the best effects were from the salicyl-bromanilin. We have, therefore, studied this case therapeutically, and I hope you have learned some valuable lessons in treatment. We have learned that sustained nourishment, stimulants, and quieting the nervous system, are the most important points in the treatment of typhoid pneumonia; if you will keep up the patient's strength the pneumonia will undergo resolution, or at least you gain time for other remedies to act.

CASES OF EARLY PULMONARY TUBERCLE TREATED BY KOCH'S LYMPH.

I wish to show you, in conclusion, two cases of early tubercular disease treated by the Koch method. As you will see from the long temperature-charts and papers, we have worked upon these cases carefully; or, rather, let us give credit where it belongs, the resident doctor and the nurses have worked most admirably and assiduously. It is no easy matter to conduct cases under Koch's treatment accurately and scientifically, because they take a large amount of time, especially because the temperature must be taken every hour or two, often at night.

I show you these two cases because I think we have had them long enough, and watched them closely enough to reach some conclusion with reference to them; moreover, they were especially selected cases out of a number that were presented to me. I choose these two cases for the following reasons: They were free from fever, or had almost no fever; there were no signs of softening; they were comparatively early cases, and in good general condition, except in so far as any disease like phthisis would impair the general condition. Moreover, we took the precaution for more than a week beforehand to study the physical signs and the sputum, the latter being carefully examined for bacilli; and we took every opportunity to watch the cases while uninfluenced by remedies. Though much alike, I will take up the cases separately.

P. C., aged twenty-five years, admitted December 22, 1890. There is no family history of phthisis. He had been working in a foundry, and subjected to sudden changes of heat and cold; had to stop work two weeks before admission. He has been growing weak and losing flesh, and has had cough for six months, but no night-sweats. He has never been ill before. The cough is very troublesome, especially at night.

The physical signs were as follows: The circumference of his chest was 34½ inches, and there was expansion of one inch. Anteriorly on the left, the percussion-note was good; on the right, dull down to the second rib. The sounds at the left apex were harsh and the expiration prolonged; at the right apex very harsh, or rather there were feeble inspiration, prolonged expiration, and dry crackling râles; below, the sounds were impaired, and there was an occasional râle; that is to say, the vesicular sound was heard, but impaired. Posteriorly at the left apex, percussion-note dull, at the middle impaired, and at the base good. On the right, percussion-note dull all the way down, and impaired in the right axilla. Therefore there was a general infiltration without any softening on the right side, with localized physical signs of a greater amount of consolidation to the fourth rib. His cough was, as I said, especially troublesome at night. The expectoration was greenish, muco-purulent, and bacilli were found in moderate quantities. There was almost no fever before he received the injections; his evening temperature was never higher than 100°, and reached that point on only two occasions; as a rule, it was 99°. Now, gentlemen, having had him under observation here before we began the injections, from December 22d to January 3d, when the first injection was made, I think we are in a position to say that he did not vary much from his previous condition; I think his cough, under rest, and the slight amount of anodyne which he took when he was unable to sleep, grew somewhat better. We began the injections with a small amount of lymph, only a milligramme, or even a little less; then we gradually increased the amount, and took the precaution of always letting a few days elapse between the injections, so as to get him back to a perfectly natural condition. We have now given him six injections. At first, after the small injections, there was very little reaction, but after the later injections there has been

very distinct reaction; on one occasion, after the injection of three milligrammes of the fluid, the temperature even reaching 104°. The full reaction from these three milligrammes, however, did not occur until the next day. I see marked on the chart another great rise, which was after four milligrammes were injected. Since then he has twice been given four milligrammes with very slight rise. Now, from four milligrammes, the third injection before the last one, the temperature went up to 103°; we know then that at present the dose, which can be given to him without much reaction, is four milligrammes.

Time will not allow me to go as fully into the description of the second case as I have into the one you have just seen, but here is the temperature-record, and you will see that there are the same rises of temperature, and tolerance after a time to the same dose as in the first case; or, rather, in the second case it requires at present a larger dose (six milligrammes) to produce the reaction. The temperature goes up now very little above the normal, at the last injection rising only to 100°. It is evident, therefore, that the dose will have to be increased, and we will give him eight milligrammes at the next injection. The dose for the first case shall be in the future five milligrammes.

Now you will want to know what effects other than the reaction have been produced in these cases—I can speak of the two cases as one, for the action has been very similar in each. Whenever there was marked reaction there were lassitude, languor, and pain in the limbs the next day, just as Koch has stated; when the reaction was slight these symptoms did not occur: in that respect our observations are entirely in accordance with the now classical description given by Koch. As regards the sputum, it undoubtedly has been very much diminished in amount, and the patients expectorate more easily. We found bacilli in abundance in the expectorated matter; some of them were living, others were materially changed, and seemed to be shorter and swollen, an effect that has been noticed by other observers. Then, again, the men say that a day or two after each injection they have a little soreness in the chest; my attention was particularly called to this in Case I., and on examination I found a friction-sound on the right side at the limit of the previous dulness, and I really think that the dulness was increased in extent; certain it was that the lung was more congested at this point, and that there was an intercurrent pleurisy. Thus there seems to have been a well-marked increase in the area of irritation or congestion in the first case. It is very significant that whenever we allowed five days to elapse without giving them anything, these fresh spots of irritation cleared up very materially, so that the pathological condition was a passing one. At present these cases are free from fever except after the injections—in that respect they are in the same condition as when the treatment was commenced.

Now, gentlemen, you will want to know something more general. I will make a few remarks concerning the constitutional effects. Undoubtedly the freeing of the expectoration, the large number of bacilli that are found in the sputum, the signs that an active process is determined in the diseased parts by the injections, have all been confirmed by a trial of these two selected cases. As regards their feelings these patients express themselves as better. and it is significant that their cough is improved; they do not cough as much at night now, and they sleep well; so that these patients have improved under no other remedy than the lymph. When we come to the graver question, namely, Are they cured? I must say no. I did not take the time this morning to go into a physical exploration of their chests, but I have done so within a day or two, and in both instances the physical signs were very little changed from those noted at the time of their admission. So that, although the signs of disease in the lungs are, strictly speaking, not improved, the general condition is improved, In the first case, however, the resident physician thinks there is a little freer breathing and a little clearing up on the right side. There are no night-sweats, but there were none before the beginning of treatment. There is but little or no change in body weight in either case.

These two cases, and other cases which I have watched, have led me almost to the following conclusions, though I admit that it is premature to come to any general conclusions concerning so new a remedy: First, that Koch's lymph is of very little use in the treatment of consumption in cases in which softening has commenced. Second, that in early cases of pulmonary consumption, and the cases before us are strikingly in favor of this view, amelioration takes place in the general condition.

These two cases are of particular interest, because no other treatment has been pursued; they are having the rest and regulated food of a hospital, but no medicines. Their cough and breathing are better. Therefore, in the early cases, amelioration unquestionably takes place in the general condition under the use of this remedy.

Now, you will ask me, Does cure take place? Is the lymph a specific? I say again that it is premature to speak of it as a curative agent; having watched cases for some time I can frankly say that I see nothing as regards the physical phenomena from which I could expect a cure, nor have I, in reading the records of cases, been able to see that any observer whose opinion is of weight has brought forward a single case in which a cure has been proved. The remedy, therefore, is applicable to the earlier cases only—giving a certain amount of relief, but I question whether, even in the early cases, it will have a distinct curative effect. This opinion does not apply to the effects of the remedy on lupus or on tubercular disease of the joints; in such cases great good has already been accomplished, but I have had no experience with it except in pulmonary tuberculosis. Again, I believe it best, when you employ the remedy, not to repeat the injections too rapidly. Let the patient completely recover from the effects of each injection.

Let me call your attention to two other points: First, no case should be treated unless we have at the same time control cases; you should select a case of almost the same character as regards extension of the disease, and put him on remedies that will for the time being relieve the cough, and see what they will do under the hospital discipline and regulated food. This is what we are doing with some cases now in the ward. Secondly, I must raise my voice against the use of this remedy for diagnostic purposes. Since the knowledge gained by the reports of recent autopsies made by Virchow, I think

it would be cruel to subject the patient to the risk of the dissemination of the disease; we do not yet know anything certain about its composition, though we have been told that it is derived from the culture of tubercle bacilli, and if used for diagnostic purposes we may disseminate tubercles in a person in whom the disease was local. Therefore, do not use this for diagnostic purposes; we have no right to subject a person to the possibility of becoming tubercular in order to settle a diagnosis which, in nine hundred and ninety-nine cases out of a thousand, can be settled by other means. I think, with our present knowledge, it is rash—criminally rash—to employ it for such a purpose.

MEDICAL PROGRESS.

A Powder for Vegetations of the External Genitals.—URRIOLA is said to use the following prescription for the removal of these growths:

℞.—Salicylic acid . . . . 30 grains.
Acetic acid . . . . 1 ounce.

This mixture may be applied once or twice a day by means of a small brush. The pain is very slight and fugacious, and Urriola believes that this treatment is preferable to any other.

Ointment for Eczema of the Nipple.—BRAUN is stated to recommend the following prescription in this condition:

℞.—Calomel . . . . 45 grains.
Carbonate of magnesia . . 40 "
Cold cream . . . . 1 ounce.

This ointment is to be applied with friction to the part which is affected. The reddened and sensitive areola which surrounds the excoriation should be anointed night and morning with the glycerole of tannin. All applications should be carefully wiped away before the infant nurses.

The Treatment of Sycosis.—ROSENTHAL recommends the following treatment for sycosis, stating that it possesses three advantages: 1st, the absence of pain; 2d, the relatively rapid cure; and 3d, facility of application.

The part which is affected should be shaved very carefully, and morning and night, for three days, the following ointment should be applied:

℞.—Tannic acid . . . . 3 grains.
Precipitated sulphur . . 30 "
Vaseline . . . . 5 drachms.

During the day the diseased area is not covered, but at night he applies an emolient ointment, consisting either of salicylated vaseline or vaseline alone. Care should be taken that no application containing lead be applied to the face during this treatment, else the sulphur will cause the formation of sulphide of lead and blacken the skin. In other cases the following prescription will be found wonderfully effective:

℞.—Tannic acid . . . . 75 grains.
Precipitated sulphur . . 2½ drachms.
Oxide of zinc, Starch } of each . . 4 "
Vaseline . . . . 1½ ounces.

This ointment should be applied morning and night, and the treatment should be completed by epilation.

An Emulsion for Tapeworm.—*La Semaine Médicale* gives the following prescription of LA MERE for the treatment of tapeworm:

℞.—Extract of male fern . . 1½ drachms.
Calomel . . . . . 7 grains.
Distilled water, Syrup of gum arabic } of each ½ ounce.
Powdered gum arabic, a sufficient quantity to make an emulsion.

Before this mixture is administered it should be well shaken, and the patient should be directed on the day previous to its use to subsist entirely upon a milk diet. It is stated that the worm will be expelled in from thirty to forty minutes after the administration of this medicament, if these directions are carefully followed. In children aged from six to twelve years, one-half this quantity should be given.

Creolin in Infantile Diarrhœa.—According to *La Semaine Médicale*, SCHWING recommends the following mixture for infants who are suffering from diarrhœa:

℞.—Creolin . . . . 1 to 3 drops.
Cinnamon water . . . 2½ ounces.
Syrup . . . . . ½ ounce.

Mix, and administer a coffee-spoonful every two or three hours. For older children, the following may be employed:

℞.—Creolin . . . . . 15 grains.
Sugar . . . . . 75 "

Mix, and divide into from five to ten powders, and administer from one to two powders each day.

Ligature of the Saphena Vein in Cases of Varicose Veins.—TRENDELENBURG (*Beiträge z. klin. Chirurgie*) advocates double ligature and division of the large saphenus vein in the treatment of varicosities of the trunk and branches of this vessel. He points out that the most dilated portions of the affected vein are below, and not, as generally supposed, above the valves. The walls of the vessel, being weaker here, yield more readily to the pressure of the blood when the valves cease to act. He also thinks that most of the blood which fills the dilated trunk and branches of a varicose saphenus vein is derived from above, and that but a small part comes from the capillaries of the foot and leg. It is this free downward pressure of blood along large and dilated vessels deprived of valves that causes the profuse and dangerous hæmorrhages, so frequently produced by a breach of the surface of the leg in which the veins are varicose. The conclusion that the results of the condition are chiefly due to the fact that the varicose branches of the great saphenus, in consequence of associated dilatation of the trunk of this vessel, are no longer separated from the cava by valves, has led Trendelenburg to treat varicosity by permanently obstructing the saphena at one point, in order to prevent the descent of the blood from the abdomen. The author refers to a series of cases in which good results followed the application of two cat-

gut ligatures near the saphenous opening and division of the vein between.—*British Medical Journal*, January 24, 1891.

Dangers of Vaginal Injections.—DR. ROULIN (*Journal de Médecine de Paris*) describes three cases of severe suffering from the use of vaginal injections. In one case the woman used a douche with the reservoir rather high. Immediately after the injection violent hypogastric and lumbar pain developed, followed by vertigo and vomiting. The abdomen was not sensitive to pressure. Metrorrhagia followed and lasted for two or three days, the pain ceasing within twenty-four hours. The second case was similar, except that the patient used a hand syringe and the symptoms were less severe. The third case also used a hand syringe, and while making the injection felt sudden pain in the abdomen and lumbar region, which was soon followed by rigors, but not by vomiting. The pain in this case also disappeared on the third day. In all these cases Roulin employed enemata of laudanum.

The cause of the pain is obscure, but the author believes that in his cases water may have entered the uterine sinuses, and insists that patients must be taught how to give themselves vaginal injections. The woman should lie on her back, should introduce the nozzle of the syringe for a short distance only, and must not inject the fluid with much force into the vagina.—*British Medical Journal*, January 24, 1891.

Chlorosis and its Treatment.—DR. FREDERICK SCHOLZ, of Bremen, has published a remarkable work on chlorosis, the outcome of observations made during the last twenty years. Instead of regarding the deficiency of iron or hæmoglobin or even that of the red corpuscles as the primary affection, he states that contraction of the vessels is always present in these cases, and this, he contends, is not to be regarded as a complication but as the primary condition, which is followed by the morbid changes in the blood. The vessels are, he thinks, too full and the blood abnormally serous. Long ago he was impressed by the cold and livid condition of the skin in anæmic subjects, and he was led by this to employ hot baths together with gentle friction, with the object of improving the vitality and nutrition by acting on the skin. The success of his first attempts was so marked that he has persevered in this line of treatment. Hot baths diminish the plethora by relaxing the tension of the vascular system, which is high, quickening the circulation, and thus relieving the palpitation, dyspnœa, and other symptoms. In thirty cases with great distress Dr. Scholz has gone a step further and supplemented the hot baths by venesection. Paradoxical as this method of treatment may appear, it was followed by marked benefit, and, if the foregoing theory of the pathology of chlorosis be correct, there can be little doubt that the course pursued by Dr. Scholz is justifiable.—*Lancet*, January 24, 1891.

Operative Treatment of Diaphragmatic Hernia.—POSTEURPSKI operates in cases of traumatic hernia through the diaphragm, by forming a flap on one side of the base of the chest, resecting one or two ribs, opening the pleural cavity and suturing the rent in the diaphragm after replacing the escaped abdominal viscera. The flap is then united, no drainage being required. Six cases have been successfully treated by this method in the hospital of Rome.—*Lancet*, January 24, 1891.

Artificial Teeth Impacted in the Larynx for Twenty-two Months.—At the recent meeting of the British Laryngological and Rhinological Association, Mr. LENNOX BROWNE reported the case of a woman in whom a plate of four artificial incisor teeth was impacted in the larynx for twenty-two months. Laryngological examinations had been made by two other physicians who thought that the trouble was due either to tuberculosis or cancer of the larynx. Mr. Browne extracted the plate by a pair of rectangular forceps, the patient being partly under the influence of chloroform. After the operation it was learned that the woman was an epileptic, and that she had awakened one morning with vomiting and dyspnœa which persisted for thirty-six hours. When she recovered from this attack her teeth could not be found, and it was assumed that they had fallen into the vomited matter and been thrown away. Up to the time of Mr. Browne's examinations it had not occurred to any one that the cause of the dyspnœa was a foreign body.—*Journal of Laryngology and Rhinology*, January, 1891.

Mouth-wash for Stomatitis.—DAVID uses the following mixture as a tonic and antiseptic mouth-wash:

℞.—Thymol	. . . . .	7 grains.
Borax	. . . . .	15 "
Water	. . . . .	1½ ounces.

A few drops of this are to be placed in a wineglassful of warm water, and the mouth rinsed with it. In cases in which the breath is fœtid, owing to deposits about the tonsils and gums, the following wash is said to be serviceable:

℞.—Borate of sodium	. . .	15 grains.
Alcohol	. . . . .	½ drachm.
Water	. . . . .	1 pint.
Thymol	. . . . .	7 grains.

Application for Toothache.—BARDET is said to recommend the following prescription for application to cavities in painful teeth:

℞.—Iodoform	. . . . .	½ ounce.
Oil of peppermint	. . .	5 drops.
Oil of bitter orange	. . .	1 drop.
Oil of lemon	. . . .	2 drops.
Tincture of benzoin	. .	1 drop.

Or, the following may be employed:

℞.—Chloroform	. . . .	2 drachms.
Naphthaline	. . . .	10 grains.

To be applied to the cavity on a small piece of cotton.

Treatment of Furuncle.—*L'Union Médicale* recommends for the treatment of furuncles washing the region which is affected with a 1-to-40 solution of carbolic acid, or, what is equally effective, with a 1-to-500 solution of bichloride of mercury. After this is done, carbolized oil may be placed over the part, and, finally, a powder composed of equal parts of iodoform and oxide of zinc. This treatment frequently causes resolution and prevents maturation of the boil.

Current Literature.

SATURDAY, FEBRUARY 21, 1891.

RESECTION OF THE WRIST-JOINT.

Dr. E. Hoffmann reports a resection of the wrist-joint with dorsal transverse incision. The case was one of extensive caries with nearly complete loss of the functions of the hand and fingers. Langenbeck's radial and Lister's ulnar incision were connected by a third one, corresponding to the articulation between the two rows of metacarpal bones. The two flaps were dissected upward and downward respectively, and the whole diseased focus removed *en masse*, including the carpal end of the metacarpal bones and the distal extremities of the radius and ulna. The diseased portions of the extensor tendons of the hand and fingers with their sheaths were also removed. The bones were approximated by periosteal catgut sutures and the ends of the carpal extensors sutured to the metacarpal periosteum and to the tendons of the extensors of the fingers. The wound was closed without drainage. Primary union followed.

Four weeks after the operation the hand was placed on a palmar splint, in the position of dorsal flexion, the fingers being left free for active and passive movements.

Union is good, and motion is satisfactory and gradually improving.

This method of operating is recommended in all graver forms of caries of the wrist-joint. The surgeon has ample room, removes the whole focus of disease without tearing the tissues and, therefore, obtains better and more rapid union.

The report of a number of ankle-joint resections by the method of Hueter, as modified by Helferich, is promised. The method consists in making a large dorsal flap of skin, fascia and tendons by a transverse metatarsal incision connecting the ends of two longitudinal incisions.—*Deutsche med. Wochenschrift*, December 25, 1890.

DIABETES INSIPIDUS AND ADIPOSITUS UNIVERSALIS.

Voss reports a case of diabetes insipidus with adipositus universalis in a girl seventeen years old.

The latter pathological condition developed after the diabetes had been present for three years, and was especially marked on the trunk. The external genital organs and the breasts were insufficiently developed, and there was primary amenorrhœa. Inosit was present in the urine in an average quantity of 0.6683 gramme per diem.

Antipyrine in increasing doses until 1½ drachms daily were given, affected neither the quantity nor quality of the urine.

With regard to the etiology of the affection, the evidence tends to show that disregarding the rare cases following insanity or trauma of the vagus, a primary polyuria must be assumed. This may be due to pathological changes in the secreting structures of the kidneys, *i. e.*, nephritis, in which case albumin is found in the urine; or to increased intravascular pressure, which in turn may be caused by abnormal propelling power or abnormal resistance in certain vascular areas. The latter condition is caused by vasomotor disturbances due to nervous impressions, as proved by Eckhard, who obtained polyuria after stimulation of the vermiform process of the cerebellum without increased intra-aortic pressure, but failed to get it after division of the splanchnics. Whether affections of the cœliac plexus have the same effect remains unsettled and doubtful.

As general causes may be mentioned, cold, insolation, intoxication (especially with diuretics), infectious diseases, scrofulosis, etc.

Any and all of these causes could be excluded in the case reported by Voss.

The development of the adipositus universalis is explained by the author in the following manner:

While the desire for food in the first four years of the disease was slight, with the development of puberty (in the fourteenth year) nature made an effort to stimulate the development of the organism, as shown by the increased desire for food; puberty, however, remaining undeveloped, the surplus food formed useless fat. At the same time the natural physiological stimulus for proper blood-formation—menstruation—being wanting, the girl became chlorotic, and thus the more predisposed to adipositus.

Regarding the action of antipyrine in diabetes insipidus, the author believes that it is most likely to do good in that form of the affection due to central nervous disease.—*Berliner klin. Wochenschrift*, January 5, 1891.

PARTURITION IN AN IRREDUCIBLY PROLAPSED UTERUS.

Faivre reports a case of parturition in a woman who had already given birth to fourteen children, and who was suffering from an irreducible uterine prolapse. The tumor protruding from the vulva was pyriform in shape, and was composed of the lower uterine segment, which was the seat of great hypertrophy and was also enormously œdematous. The lips of the os were lacerated and extensively ulcerated. The greatest circumference of the mass was thirteen and one-half inches; the distance from the clitoris to the angle formed by the union of the anterior wall of the vagina and the base of the prolapse—most of this surface being ulcerated—was five and one-half inches; from the clitoris to the os, seven and one-half inches; from the fourchette to the union of the base and posterior vaginal wall, two and three-fourths inches. When the woman came under Faivre's care she was confined to bed, the foot of the cot being elevated by three bricks placed under it, and was not permitted to raise herself. Under the influence of these measures the prolapsed mass notably diminished in volume and became less œdematous. The genu-pectoral position, assumed for varying periods of time, was found to be of no service and to give rise

to much suffering. Gestation being protracted beyond the normal limit, it was decided to interfere with its further progress. The patient was anæsthetized by chloroform, Barnes's small forceps were applied, and the child was delivered by traction and expression combined. For several days after delivery the mass protruding from the vulva gradually decreased in size and the woman's condition improved. This diminution ceasing, perineorrhaphy was performed three weeks after delivery, with temporary relief. Some months later it was found necessary to perform a combined operation upon the vagina and uterus, consisting in a high amputation of the neck, a large, anterior colporrhaphy, a colpo-perineorrhaphy, and shortening of the round ligaments, which resulted in an absolute cure.

It is evident that, in this case, taking into consideration the irreducible nature of the prolapsed portion of the uterus, the contractile efforts of the uterus were exhausted upon the mass instead of acting upon the cervical canal and expelling the fœtus. A second difficulty, and one which was an insurmountable obstacle to delivery, was the resistance offered by the enormously hypertrophied and rigid cervix, upon which the already weakened muscular forces had absolutely no effect.—*Archives d' Obstétrique et de Gyncologie*, December 25, 1890.

THE OPERATIVE TREATMENT OF TRICHIASIS AND DISTICHIASIS.

OF the two principal operative methods in the treatment of distichiasis and trichiasis, that of Jaesche-Arlt and that of Snellen, RAEHLMANN prefers the former for the majority of cases. Its principal advantage lies in the fact that the apposition of the inner margin of the lid to the ocular conjunctiva is not disturbed, and the eye retains its physiological protection, while in resection of the tarsal cartilages (Snellen) the whole lid with its internal margin is lifted away from the eyeball.

Raehlmann holds that the entropium cannot be produced by the action of the central fibres of the orbicularis palpebrarum—the muscle which he, like Jacobson, considers the chief causative factor of entropium—if the conjunctival surface of the lid, and especially its margin, remain in apposition to the ocular conjunctiva.

If, therefore, after trachoma the hollows of the curved cartilages are completely filled with scar-tissue so that the inner surface of the lid fits the globe of the eye, entropium does not result, but is inevitable if softening of the cartilage and its curvature occurs.

In the latter cases Snellen's operation is indicated. Both methods are perfected by transplantation of skin or mucous membrane as originated by Thiersch.

In the course of the last six months seventy-four transplantations of this kind were performed in the author's clinic. While in former years he, as well others, had numerous failures due to shrinkage and necrosis of the transplanted flaps, in this series failure resulted in only two cases. These excellent results he attributes to the perfected technique of the operation, consisting preëminently in the preparation of the transplanted flap, and also in the exact apposition by sutures.

The margin of the lid is first split, and while the surfaces are cleansed and the hæmorrhage *completely* stopped, the flap is prepared as follows: After resecting a piece of skin and subcutaneous tissue, it is placed with the epidermal side downward on a warm porcelain plate, and all tissue is removed down to the rete Malpighii, till a yellowish-gray, pale, and nearly diaphanous surface remains.

This preparation has several advantages: First, since the remaining fibres run in the direction of the surfaces and not obliquely or vertically to them, as in the subcutaneous tissue, curling in of the edges is prevented and exact apposition facilitated; second, the elasticity of the flap is decreased and shrinkage less liable to occur; third, all hair-follicles are removed, and hence the development, after the operation, of hairs in the transplanted portion is prevented. The flap is always cut larger than the fresh surfaces on the eyelid.

Through the sides and the extremities of the flap needles are passed from the epithelial surface. The flap, with the epithelium still downward, is now transferred to a piece of linen, and while the assistant presses it into the gaping wound the stitches are inserted. As soon as the flap becomes red, usually on the third day, the stitches in the longer edge are removed, and a day later those in the corners. The operation has the further advantage that no special bandage or special attendance is needed, and many of Raehlmann's patients did not even leave their occupation.

Since the author found that flaps of mucous membrane are more liable to shrink and to be thrown off, he has used skin-flaps exclusively in canthoplasties; but transplantation of mucous membrane has several times been employed as a substitute for lost conjunctival tissue in cicatricial symblepharon.

Raehlmann obtained relatively good results by transplantation of flaps of skin and of mucous membrane in extensive retraction of the ciliary margin in order to lengthen the lid. This double transplantation is applicable to cases in which, according to Klarer, the anterior margin with ciliæ has been removed and later a contraction has taken place—and to a still greater extent it is indicated in xerosis of the mucous membrane. — *Deutsche medicinische Wochenschrift*, January 1, 1891.

THE ARTICULAR AND PERI-ARTICULAR COMPLICATIONS OF DIPHTHERIA.

DR. M. B. LYONNET thoroughly reviews the subject of articular and peri-articular disorders consecutive to diphtheria. These complications he has found are very rare, and he declares that, in the language of Trosseau, "diphtheria does not like the articulations." Although the complications are rare, cases are on record in which serious involvement of the joints in an inflammatory process greatly prolonged convalescence from diphtheria. It is evident that this arthritis is quite distinct from acute articular rheumatism.

The production of the arthritis may be explained in three ways:

1. In certain cases it may be due to the simple localization of the pathogenic germ upon the articular serous membranes. It is caused, in short, by a generalization of the primary microbic infection, as in the experimental arthritis produced by Max Schuller, and more recently by Babinsky and Charrin (*Société de biologie*, July 27, 1889, and *Société anatomique*, July, 1889), in rabbits suffering from pyogenic diseases.

2. In other cases it may not be charged directly to the microbes, but rather to their soluble products, which have been well studied by Gaspard, Panum, Bergmann, and others. It is in these cases that examination of the effused fluids does not reveal the infectious agents.

3. The complications may be due to other microbes than those of the primary affection, which, finding an avenue of entrance, proliferate in the synovial fluid. These are the secondary infections now well investigated (Roger, *Gazette des hôpitaux*, 1890), and which, according to Charrin (*Les infections secondaires, Journal de pharm. et de chimie*, 1889), result in a penetration into the organism of "a second microbe, which adds its influence to that of the first."

The latter and most recent theory explains how erysipelas, due to the streptococcus of Fehleisen, can, for example, complicate typhoid fever, due to the bacillus of Eberth.

Ordinarily the effusion into the joints remains serous, but it may become purulent. The affection shows a predilection for the knee-joints, probably because these articulations are more exposed to external influence, more constantly used, and have a much larger lymphatic circulation. Still, it may be said, that the true cause of the predilection is unknown. In these articular affections the prognosis is usually good, but recovery is often slow. In some cases the salicylates have been successful.

Dr. Lyonnet draws the following general conclusions from the facts which he has investigated:

1. The articular complications of diphtheria are very rare, but we cannot deny their existence, since undoubted cases have been reported (Pauli, Bokaï, Eichorst, Henoch, and Dauriac).

2. These complications are usually due to secondary infection. They are, then, acute or subacute inflammations, ordinarily serous, sometimes purulent. They appear, either in the course of, or oftener, during convalescence from, diphtheria.

3. Together with these arthrites there exist periarticular trophic disturbances due to a nervous lesion. There is hyperplasia of the tissues of the region occurring after multiple symptoms of poisoning of the nervous system, and a long time after the beginning of the sickness.—*Lyon Médical*, January 4 and 11, 1891.

REVIEWS.

TWELVE LECTURES ON THE STRUCTURE OF THE CENTRAL NERVOUS SYSTEM, FOR PHYSICIANS AND STUDENTS. By DR. LUDWIG EDINGER. Second revised edition. Illustrated. Translated by W. H. Vittum, M.D. Edited by C. Eugene Riggs, M.D. F. A. Davis, 1890.

To all students, and to most physicians, the study of the anatomy of the higher nervous system, particularly in relation to its various functions, is most difficult, chiefly because so many names are applied to the same thing as to produce much confusion. If one turns to a work on physiology he may, perhaps, find one or two illustrations which will aid him in his studies, but on the next page he will find others which hopelessly confuse him, and perhaps, lead him to wrong conclusions.

Edinger's lectures, published in book form, probably give the best series of both crude and diagrammatic illustrations that have yet been placed before the profession, and the text which accompanies them, having felt the touch of Dr. Eugene Riggs, of St. Paul, is sufficiently clear to aid the reader in acquiring the meaning of the various German words with which the cuts are largely dotted. The marking of the various tracts and other portions of the nervous system with the terms which are used by our German colleagues is certainly a mistake in a book in which the text is English, and necessitates a small vocabulary being attached to each picture. In other instances figures occur, which in the original probably referred to sentences in the text, but which have no reference in the American edition. With the exception of these faults, we have nothing to say except in praise, and we congratulate Dr. Riggs and Dr. Vittum upon their valuable contribution of German literature to the library of American physicians.

AN ILLUSTRATED ENCYCLOPÆDIC MEDICAL DICTIONARY: BEING A DICTIONARY OF THE TECHNICAL TERMS USED BY WRITERS ON MEDICINE AND THE COLLATERAL SCIENCES, IN THE LATIN, ENGLISH, FRENCH, AND GERMAN LANGUAGES. By FRANK P. FOSTER, M.D., with the Collaboration of Eleven other Physicians. Vol. II. D. Appleton & Co., 1890.

THE second volume of this enormous work has just appeared, and presents all the features which caused both praise and blame to be attached to Volume I. The praise should, in this instance, be directed to the editor and his assistants, who have compiled so far the most exhaustive of dictionaries; while the blame, if it is proper to use such a word, is deserved by reason of the unwieldy manner in which the material is presented to the reader. This fault is, nevertheless, a necessary one in a reference book so complete in every detail.

A special characteristic is the lucidity of the definitions, which are not only clear, but sufficiently complete to really give one some information. This is the chief fault of several of the dictionaries, both large and small, which have appeared of late, for in many instances they are so cross-referenced as to be of little real service. Another advantage is the close resemblance of Foster's Dictionary to Webster or Worcester in respect to the methods employed in giving the pronunciation and etymology of words, while these standard works are

surpassed by the insertion of all words used in the discussion of medicine, botany, or their allied sciences. Hundreds of words in our own tongue startle the reader at the thought that he has not heard of such terms before, and every page presents a mine of wealth to its fortunate possessor. The illustrations are particularly well executed, and the publishers' work cannot be surpassed.

With this brief notice of one of the most stupendous tasks which medical men have ever set themselves to complete, the reader must be satisfied. To criticise the volume would be both beyond our ability and a work of supererogation; and if the eagle eye of some devotee of etymology can discover in the mass of information food for just criticism, his task is but an ungracious carping which will be buried in the splendor of a great literary achievement.

The thoroughness of the work prevents its rapid appearance before the purchaser, and has caused rival firms to state, with some show of fact, that the volumes would never be completed. This unfortunate occurrence will not take place, but we hope that the rest of the dictionary will be more rapidly finished. The second volume includes from "Cac" to "Fasay," and is made up of 1544 double-column pages.

A LABORATORY MANUAL OF CHEMISTRY, MEDICAL AND PHARMACEUTICAL. By OSCAR OLDBERG, PH.D., and JOHN H. LONG, SC.D. Illustrated; second edition, revised and enlarged. Chicago: W. T. Keener, 1891.

THE title of this work of 459 pages indicates exactly what will be found between its covers, for it is only of value to the physician who is interested in making tests in a private laboratory, or to the student of medicine and of pharmacy, who is taking a course in chemistry. The book is copiously illustrated for the purpose of showing how various pieces of apparatus are to be employed, and contains, among other things, tables showing the approximate solubilities of a large number of drugs both in alcohol or water. Lists of apparatus which will be needed by everyone who is about to fit up a laboratory for private use are given, and a long list of re-agents and test solutions is also inserted. The type is large and the paper is good, while the reputation of the authors assures the purchaser that he will obtain a useful guide. The only thing that we find to object to is the employment of such ancient terms, as "aqua regia" and "oil of vitriol," which have long since passed out general use with scientific men.

NEWS ITEMS.

Health of New York State in 1890.—The New York State Board of Health has prepared its mortality sheet for 1890, giving the totals by eight districts, by months, and by certain principal causes. The deaths numbered 116,830, in an estimated population of 6,000,000, which, with certain corrections for non-reported mortality in some rural sections of the State, makes a death-rate of 19.6 per 1000. The mortality in the first half-year was greatly exaggerated by epidemic influenza, from which cause alone it is estimated that 5000 deaths took place. Many deaths from this disease were certified to under the head of acute respiratory causes, so that this group has had to be credited with a mortality of 18,000, which is abnormally high in comparison with the corresponding totals of recent years. Smallpox caused only four deaths, while scarlet fever showed a decline of about 30 per cent. Diphtheria also showed a moderate decline, while measles was marked by an increase. From consumption there were 13,800 deaths, a smaller proportionate mortality than has been reported during the past five years. Cancer caused 2868, old age 5484 deaths.

Mortality in Chicago.—The report of the Chicago Health Department for the last year shows that during 1890 there were 21,856 deaths, making a percentage based upon a population of 1,200,000, of 18.21 per one thousand. Of the deaths 9.95 per thousand were in children under five years of age, and seven in persons older than one hundred years. *La grippe* directly caused 112 deaths, but pneumonia and other complications with the influenza swelled the number of victims of this class of diseases. Pneumonia carried off 2073; consumption, 1972; bronchitis, 1189; typhoid fever, 1008; scarlet fever, 193; malarial fever, 121; whooping-cough, 201; murder, 77; suicide, 206; delirium tremens, 114; and hydrophobia, 2. The total number of deaths from tubercular diseases was 2231.

Railway Surgeons.—It is only ten years since the first organization of the surgeons of railroads was attempted in the formation of an association of the medical officers of the Wabash railway. This example was slowly followed along the great lines of traffic until it became possible to form the large and influential National Association. This voluntary union has resulted not only in an improved status of the surgeons themselves, but also in an increased efficiency of the medical service along the lines. The importance of this branch of the railway service seems to be fitly recognized in the establishment of a department devoted to railway surgery n the *Railway Age* of Chicago, under the able supervision of Dr. Harvey Reed, of Mansfield, Ohio.

Warren Triennial Prize.—The Warren Triennial Prize was founded by the late Dr. J. Mason Warren in memory of his father, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation, considered worthy of a premium, on some subject in pathology, surgery, or pathological anatomy; the arbitrators being the Physicians and Surgeons of the Massachusets General Hospital.

The subject for competition for the year 1892 is on some special subject in physiology, surgery or pathology.

Dissertations must be legibly written, and must be suitably bound so as to be easily handled. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation.

Any clue given by the dissertation, or any action on the part of the writer which reveals his name before the award of the prize, will disqualify him from receiving the same.

The amount of the prize for the year 1892 will be $500.

In case no dissertation is considered sufficiently meritorious, no award will be made.

A high value will be placed on original work.

An Army Medical Board will be in session in New York City, N. Y., during April, 1891, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 1, 1891, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon General U. S. Army, Washington, D. C.

C. SUTHERLAND,
Surgeon General U. S. Army.

The following is the general plan of the examination:

I. The physical examination will be rigid; and each candidate will, in addition, be required to certify "that he labors under no mental or physical infirmity, or disability of any kind, which can in any way interfere with the most efficient discharge of any duty which may be required."

II. Oral and written examinations on subjects of preliminary education, general literature, and general science. The Board will satisfy itself by examination that each candidate possesses a thorough knowledge of the branches taught in the common schools, especially of English grammar, arithmetic, and the history and geography of the United States. Any candidate found deficient in these branches will not be examined further. The examination on general science will include chemistry and natural philosophy, and that on literature will embrace English literature, Latin, and history, ancient and modern. Candidates claiming proficiency in other branches of knowledge, such as the higher mathematics, ancient and modern languages, etc., will be examined therein, and receive due credit for their special qualifications.

III. Oral and written examination on anatomy, physiology, surgery, practice of medicine, general pathology, obstetrics and diseases of women and children, medical jurisprudence and toxicology, materia medica, therapeutics, pharmacy, and practical sanitation.

IV. Clinical examinations, medical and surgical, at a hospital, and the performance of surgical operations on the cadaver.

Due credit will be given for hospital training and practical experience in surgery, practice of medicine, and obstetrics.

The Board is authorized to deviate from this general plan whenever necessary, in such manner as it may deem best to secure the interests of the service.

The Board reports the merits of the candidates in the several branches of the examination, and their relative merit in the whole, according to which the approved candidates receive appointments to existing vacancies, or to vacancies which may occur within two years thereafter. *At the present time there are five vacancies to be filled.*

An applicant failing in one examination may be allowed a second after one year, but not a third.

No allowance is made for the expenses of persons undergoing examination, but those who are approved and receive appointments are entitled to transportation in obeying their first order assigning them to duty.

Operative Treatment of Chronic Disease of the Uterine Appendages.—The following letter from Williams and Champneys, which appears in the *British Medical Journal* of February 7, 1891, touches upon a subject of great interest to us all, and of peculiar interest to our English cousins. The vagaries of Lawson Tait, and his utter disregard of facts when he makes statements, coupled with his indiscriminate operative tendencies, should aid very greatly in the acceptance of the views advanced by these progressive representatives of British gynecology:

"The recent discussions on the diseases of the uterine appendages at the Medical Society and elswhere have brought this subject prominently before the profession.

"Affections of the uterine appendages are nothing new; they are comprised under the name pelvic peritonitis, or perimetritis; and since the writings of Bernutz in 1860–62, it has been well known, though not until lately current, that in a large number the route and sometimes the focus of infection have been the tubes.

"A change in nomenclature has arisen, for words ending in "salpinx" have displaced the older and more general names. Yet further changes have arisen in practice in some quarters, in that these affections have become the objects of innumerable operations. Now perimetritis is probably the very commonest of all the serious diseases of women. It is also perfectly certain that the great majority of cases get quite well without any operation. We are far from denying that exceptional cases call for surgical procedures, or that cases of prolonged suppuration of the pelvis are properly treated by the application to them of ordinary surgical principles. But this wholesale resort to a mutilating operation, advocated by several speakers at these discussions, calls for serious consideration by the profession. We have both been in charge for many years of the obstetric and gynecological departments of two of the great general hospitals of London, besides private practice. During that time thousands of patients have passed through our hands, and a very large number of cases of pelvic inflammation. We have on the rarest possible occasions resorted to removal of the appendages, and never unless life seemed to be threatened, or the health had been greatly impaired for many months. We never have sent patients away after a course of Epsom salts, 'and when this drug fails have folded our hands, and expressed the deepest sympathy with the sufferer.' On the contrary, our patients have generally got well by the use of patience

on their part and on ours. If, after a long course of patient treatment, it has seemed to us imperative to operate, we have been ready to do so, and have done so in rare instances. Without patience, many women, who have had matting of the pelvic organs for months, but who have perfectly recovered and have borne children, would have had their uterine appendages removed.

"Statistics on matters of this kind are often given in a manner which does not bring out important points. For instance, in the discussion at the Medical Society, it would have been interesting to know (1) the total number of women seen during the period embraced by the table, and (2) the total number of cases of perimetritis or pelvic inflammation among them. Statistics without these facts may give information as to the chances of the operation; those indicated would give the chance of being operated upon.

"A plea for patience is to be found in the declaration of the operators that 'the full benefits of the operation are not usually felt for months or years after.' If the operator would exercise this patience before the operation, there might be the less need for its exercise by the patient after the operation. To operate after a 'couple of months' is, in our opinion, quite unjustifiable in chronic cases, or in any except those of peril to life. To remove the ovaries in cases of congenital ill-development with dysmenorrhœa and sterility and anteflexion of the uterus, is a proceeding we have never seen necessary to recommend.

"Death from disease of the appendages is of extreme rarity, but the mortality after the operation is considerable. It is inconceivable to us that this amount of operating is justifiable, and we beg to protest in the strongest manner against it.

"This particular operation has already furnished material for legal proceedings in a well-known case. It is conceivable that it might form the object of legislation. We cannot think that the good sense of the profession can fail to be roused against it. The sooner the better. There are several other questions requiring an answer, some of which have been referred to by others; for instance, What were the results in the unreported cases? What are the dates of the reported cases? What were the results in general surgery at the Waterloo Bridge Road Hospital during the time of the unreported cases? These are questions concerning the authorities of that hospital. But we prefer to keep to our point, and to repeat our protest against the removal of the appendages whenever a tumor of them is found accompanied by pain and hæmorrhage; or a dilated tube; or affections of the tubes with tender or even enlarged ovaries, after treatment has been tried for a couple of months; or when a woman suffers from pelvic pain, dysmenorrhœa, or dyspareunia, after one or more attacks of pelvic inflammation; or in cases of ill-developed ovaries with anteflexion and dysmenorrhœa; or in cases of cardiac dyspnœa; or of tubercular disease of the tubes associated with similar disease of other organs; or in neurotic women without disease of the appendages. We protest against the view that any one of the above conditions diagnosed before, or discovered during or after, an operation, is in itself a justification for the removal of the uterine appendages; and such practice is, in our opinion, highly injurious to women and to the profession. In no other department of surgery is inflammation of an organ considered to justify its removal."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 10 TO FEBRUARY 16, 1891.

By direction of the Secretary of War, CHARLES C. BYRNE, *Lieutenant-Colonel and Surgeon*, is relieved from duty at Fort Sam Houston, Texas, and will report in person to the commanding general Department of the Columbia, for duty as Medical Director of that Department, relieving Bernard J. D. Irwin, Colonel and Surgeon. Colonel Irwin, on being relieved by Lieutenant-Colonel Byrne, will proceed, via San Francisco, California, to St. Louis, Missouri, and report in person to the commanding general Department of the Missouri, for duty as Medical Director of that Department, relieving Charles Page, Colonel and Assistant Surgeon-General. Colonel Page, on being relieved by Colonel Irwin, will report in person to the commanding general Division of the Atlantic, for duty as Medical Director of that Division.—Par. 6, *S. O. 36, A. G. O., Washington, D C.*, February 13, 1891.

By direction of the Secretary of War, LOUIS M. MAUS, *Captain and Assistant Surgeon*, is relieved from further duty at Fort Stanton, New Mexico, and will report in person to the commanding officer Whipple Barracks, Arizona Territory, for duty at that station, relieving Richard W. Johnson, Captain and Assistant Surgeon. Captain Johnson, on being relieved by Captain Maus, will report in person to the commanding officer, San Carlos, Arizona Territory, for duty at that station.—Par. 7, *S. O. 35, A. G. O., Washington, D. C.*, February 12, 1891.

JOHNSON, R. W., *Assistant Surgeon.*—Is granted leave of absence for one month, to take effect on or about February 10th, instant.—Par. 1, *S. O. 16, Department of Arizona, Los Angeles, California*, February 4, 1891.

WOLVERTON, WILLIAM D., *Major and Surgeon.*—Is granted leave of absence for one month, to take effect on or about February 15, 1891.—Par. 2, *S. O. 15, Department of the Platte, Omaha, Nebraska*, February 7, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 14, 1891.

AUZAL, E. W., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Boston," and ordered to the U. S. S. "Lancaster."

CRAIG, T. C., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Vesuvius," and ordered to the U. S. S. "Boston."

BRAISTED, W. C., *Assistant Surgeon.*—Detached from Hospital, Hot Springs, and ordered to the U. S S. "Vesuvius."

FITTS, H. B., *Passed Assistant Surgeon.*—Ordered to the Army and Navy Hospital, Hot Springs.

ARNOLD, W. F., *Assistant Surgeon.*—Ordered to the U. S. Receiving-ship "Vermont."

BLACKWOOD, N. J., *Assistant Surgeon.*—Detached from the U. S. S. "Vermont," and ordered to the U. S. S. "Newark."

ASHBRIDGE, RICHARD, *Passed Assistant Surgeon.*—Ordered to the Navy Yard, New York.

NORTH, J. H., *Assistant Surgeon.*—Detached from the Navy Yard, New York, and ordered to the U. S. S. "Lancaster."

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

INTERESTING AURAL CASES.

BY S. G. DABNEY, M.D.,

PROFESSOR OF PHYSIOLOGY AND CLINICAL LECTURER ON DISEASES OF EYE, EAR, AND THROAT IN THE HOSPITAL COLLEGE OF MEDICINE; VISITING SURGEON TO THE EYE AND EAR DEPARTMENT OF THE LOUISVILLE CITY HOSPITAL.

Fracture of the tympanic portion of the temporal bone.—According to Buck (*Diseases of the Ear*, p. 290), fractures of the temporal bone may be classified as follows: 1. Fracture or diastasis of the tympanic or squamous portion in the region of the middle ear, without implication of the pars petrosa. 2. Fracture of both the tympanic and petrous portions. As the last-named variety is, of course, much the more serious, the recognition of this distinction is of much practical importance. The following case illustrates fracture of the tympanic portion. It will be observed that the tuning-fork was heard better on the bone than in the air, that there was at no time any watery discharge from the ear, and that the hearing improved from $\frac{\text{pressure}}{\text{XL}}$ soon after the injury to about $\frac{2}{\text{XL}}$ a few weeks later. The ordinary hearing-distance for my watch is forty inches.

A. B., aged twelve years, while sliding down a banister fell, striking his left shoulder and the left side of his head against the floor. For about two hours afterward he was unconscious. There was a discharge of blood from the ear which, though slight, recurred from time to time for about a day and a half. There was no watery discharge. The patient remained in bed two days. No pain was complained of. On getting up he was somewhat dizzy, his gait was unsteady, and vision with the eye of the injured side was blurred. Hearing in the corresponding ear was greatly impaired. These symptoms, namely, deafness in the affected ear, blurred vision in the eye of that side, and unsteadiness of gait, remained when the patient visited me five days after his fall. Examination then gave the following results: Watch heard only on pressure; tuning-fork (C_2) heard louder on the mastoid than in the air in front of the ear; the membrana tympani was very red and its exact conditions concealed by this acute congestion. The vessels of the optic nerve of this side decidedly congested; vision in this eye rather less than $\frac{20}{\text{XX}}$, in the other more than $\frac{20}{\text{XX}}$. From these symptoms the opinion was expressed that there had been a fracture in the temporal bone, and that the hearing, though permanently injured, would probably undergo some improvement, and that the ocular symptoms would disappear. This prognosis seemed warranted by the tuning-fork test and by the absence of any decided evidences of inflammation. Ten days later, the blurring of vision had disappeared, the gait was again all right, and the hearing was $\frac{2}{\text{XL}}$. At this time a line could be seen running into the upper, anterior part of the drum-membrane, probably indicating the site of a rupture. The membrana tympani was still very red and the ordinary landmarks indistinct.

A case of "Ménière's disease."—Mr. B., aged fifty years, consulted me recently for deafness and "ringing" in his right ear. He gave this history: Had never had syphilis; was addicted to the rather excessive use of alcoholic stimulants, but had not been on a "spree" lately; his general health was good. Two weeks prior to his calling on me, about four o'clock in the afternoon, he suddenly—"quick as a stroke of lightning," he expressed it—became very deaf in his right ear, and was attacked with violent tinnitus aurium, together with vertigo so intense that he was unable to sit in his chair. With the help of friends he was carried to his home, a short distance away, and put to bed. A few hours later intense nausea and vomiting ensued; the deafness and tinnitus remaining unchanged, and the vertigo still so intense that he was unable to sit up. By the next morning the nausea had disappeared and the noises in the ear were better, but the vertigo remained and confined him to bed for several days. When he visited me, ten days later, the only subjective symptoms were the deafness and tinnitus. My watch (normally heard at forty inches) was not heard even on pressure. The tuning-fork, sounding loudly, could be heard neither in the air nor on the bone; placed on the forehead it was distinctly heard in the good ear, but not in the deaf one. The membrana tympani of this side was a little dull in color and the light spot small, but these conditions were also found in the opposite ear, in which the hearing was good. Inflation by Politzer's method was felt in both ears, but did not affect the hearing. Examination of nose and naso-pharynx showed a condition as healthy as is usual in this climate.

Notwithstanding a negative history as to syphilis, the "mixed treatment" was administered for some weeks, but without effect. The deafness remained, and the noises became less, but did not cease.

The prevailing opinion is that cases such as the one just related are due to a primary disease of the labyrinth; probably, in this instance a hæmorrhage—but in the absence of a post-mortem the diagno-

sis of the exact pathological condition must be largely conjectural.

Restoration of the membrana tympani, and cure of suppurative otitis of ten years' standing.—Though there is nothing novel in the symptoms or treatment of the following case, it may be of value as showing the good result often attained by simple measures carefully executed.

H. W., a pale, "flabby" boy, fifteen years old, was referred to me for disease of the left ear on September 1st. The history given by himself and his mother was that he had had a "running from the ear" since his early childhood; occasionally acute exacerbations with intense earache would occur; he had suffered from such an attack for the last ten days; poultices had been applied a great part of this time, but though the discharge was lessened, pain continued and the ear felt stopped up. My watch (normally heard forty inches) was heard only on pressure. Several polyps were seen in the auditory canal, completely filling its deeper portion. The patient was extremely nervous and unmanageable, and it was found impossible to operate without general anæsthesia. In the meantime, cod-liver oil and iron were prescribed, the poulticing forbidden, and a douche of hot water was ordered. On September 3d chloroform was given by Dr. Walter Roberts, and under its influence I removed with Blake's snare the polyps from the auditory canal. The patient visited me at my office again on September 5th. Examination now showed the membrana tympani reduced to a narrow ring at the edge, a polyp growing from the tympanic wall anteriorly and the attachments of the polyps removed from the auditory canal plainly visible. I syringed the ear with a solution of bichloride of mercury, 1 : 3000, instilled a few drops of a four per cent. solution of cocaine, and after pricking the polyp with a sharp needle, rubbed into it and into the roots of those removed from the canal, a bead of nitrate of silver, fused on the end of a probe. There was at this time profuse suppuration. This treatment was continued daily for several days. When the polyps had been destroyed, suppuration was very much diminished. From this time on, the ear was carefully syringed with the bichloride solution and powdered boric acid blown into it three times a week. The membrana tympani was being rapidly regenerated and at each visit its approach to the centre was more evident. As the suppuration disappeared, the patient was required to call at my office only once a week and the same treatment continued. By October 10th there was a complete membrana tympani with no vestige of a perforation. Hearing-distance for my watch was eight inches.

The Druidic Banchoreion.—According to the last report on medical colleges of the Illinois Board of Health, two diplomas of the Druidic Banchoreion of Buffalo, N. Y., were offered to the Board of Medical Examiners of Montana for the purpose of obtaining license to practise medicine, but were not accepted. Several diplomas of "this concern" are registered in New Jersey.

EXPERIMENTAL STUDIES IN INTESTINAL SURGERY.

BY WILLIAM E. ASHTON, M.D.,
AND
J. M. BALDY, M.D.,
OF PHILADELPHIA.

OUR object in presenting this paper on intestinal surgery is to give a description of the methods and technique of the work we have done on the lower animals, so that surgeons who are unacquainted with this most important branch of surgery, and who desire to fit themselves to meet successfully the indications which arise from intestinal injuries or disease in man, may have a guide by which they can operate. We also desire to give to the profession such practical points on the surgery of the intestines as will not only increase success in operative work, but which will, at the same time, greatly increase the rapidity of manipulation. Abdominal surgery stands alone in that success is absolutely dependent upon familiarity of detail and rapidity of work. If no shock from a prolonged operation has been sustained, the patient's chances are increased a hundredfold. Given, for example, a case of intestinal obstruction, resulting in gangrene and stercoraceous vomiting, with the patient bordering on collapse, can any surgeon hope to save his patient if he takes from one to two hours in making an artificial anus or in doing a lateral anastomosis with or without resection?

We pass at once to a description of the technique and instruments used in intestinal surgery.

Instruments.—A skilful abdominal surgeon is always known by the simplicity of his outfit and the small number of instruments that he requires. With the following armamentarium we are able to perform all the various operations on the hollow viscera: four pairs of hæmostatic forceps, a knife, a pair of scissors, needles, silk, silkworm-gut and catgut sutures, rubber ligatures and rings, and a few sponges and towels. A special pair of forceps for invagination will be found useful, but in most of our operations we used for this purpose hæmostatic forceps.

The knife, scissors, and hæmostatic forceps should be those used in general surgical operations. The invagination forceps should have long slender blades, at least an inch and a half in length. If the blades of this instrument be too short it is difficult to make the invagination.

Needles.—For the abdominal walls the long, straight, spear-pointed needles are the best. The needles used on the intestines should be long, straight, and thin; they should have as large an eye as the shaft will permit, without the needle being wider at the eye than in the shaft. Darning needles ("Sharps, No. 6") fulfil these indications better than any others that we have used.

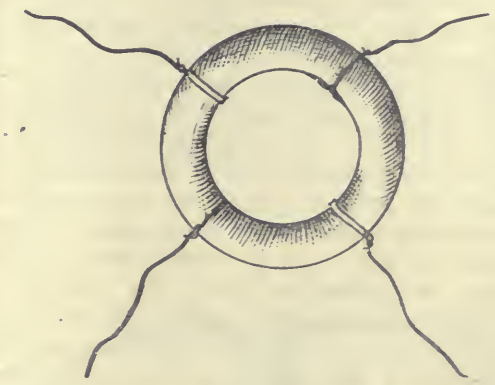
Sutures and ligatures.—For the abdominal walls we prefer silkworm-gut. In the end-to-end invagination and in the implantation of the ileum into the colon it is necessary to make use of catgut, which should be heavy enough not to break readily. For all other purposes we found pure Chinese twisted silk, No. 1, the best. This material is strong enough to stand the traction necessary in tying, it is large enough not to be lost sight of during the operation, it is sufficiently rough not to slip through the fingers while being used (as pure silk will do), and it is readily threaded into the No. 6 darning-needle. For the ligation of bleeding vessels we use the same silk.

Rubber ligatures.—It is necessary to prevent fæcal matter from invading the seat of operation during the manipulation. For this purpose many contrivances have been suggested and found useful. Nothing, however, is better than small rubber drainage-tubing, eight or ten inches in length. Ordinarily, two such ligatures are sufficient, but in an implantation of the ileum into the colon, for instance, it becomes necessary to make use of four.

Rings.—Most experimenters have been dissatisfied with the materials used for approximation rings, and have made an effort to improve upon them. We also have fallen victims to this desire, and have been using a ring which we believe has some distinct advantages. The material used is solid rubber cord, $\frac{1}{8}$ of an inch thick, and from $2\frac{1}{2}$ to 3 inches in length, according to the size of the animal to be operated on. For the human gut, which is larger than that of an ordinary dog, it is better to use a cord $\frac{3}{16}$ of an inch thick and $3\frac{1}{2}$ inches in length, or even longer if necessary. It is advisable to have rings of several sizes on hand during an operation.

In making these rings the cord is cut into either two or four segments, which are united, in the form of a circle, with catgut. The approximation ligatures, four in number, and made of Chinese silk-twist, No. 1, are tied to the catgut holding the different segments together. If the rings be made of two segments, as we usually make them, a strand of catgut is tied around the cord on either side, midway between where the sections are joined together. The approximation ligatures are fastened to them in the usual manner (see Fig. 1). These ligatures are threaded in the needles already described, and the ring is then ready for use. We claim for this ring many good points. It has a large opening, and the approximation surface is small and does not take up so much valuable room as many others do, at the same time the resulting approximation is sufficiently broad and firm. Again, these rings are solid, thus holding the parts perfectly immovable and also keeping the communication between the intestines wide open. The firmness of these rings also makes them much easier to manipulate. Further, they are easily and quickly made at a trifling cost. The catgut holding the segments of the ring together is gener-

FIG. 1.



Approximation ring ready for use.

ally found to be in good condition as late as the fifth or sixth day. We have never known it to become absorbed early enough to interfere with the success of the operation. These rings would be perfection were they only absorbable.

With the exception of Brokaw's hollow rubber rings, other rings have too broad an approximation surface. In other words, they take up too much room in the gut and give too small an opening. The same is true of Senn's bone-plates, Penrose's rubber disks, Abbe's catgut rings (which in addition are not always absorbed, as proved by Van Lennep and Shimwell), Davis's catgut mats, and Robinson's rawhide plates. Excepting Senn's plates, they all are too pliable, or at least become so soon after being placed in position. Again, with the exception of the Penrose disks, they are too difficult to make and are expensive, and for some it is impossible to obtain the material. The ligatures in Senn's plates are so complicated as to make them dangerous. The Brokaw rings more nearly approach the advantages of our own.

For end-to-end invagination or for implantation of the ileum into the colon an entirely different kind of ring is required. This ring must be small enough to be introduced into the gut and as thin as is consistent with the necessary firmness. The surface must be comparatively broad. The best material for this purpose is the larger-sized rubber bands found in the shops, which are used for holding together bundles of paper. The bands should be fully half an inch broad and about one-sixteenth of an inch thick. They can be cut into strips of the required length, according to the calibre of the gut. The ring is then made by stitching the ends together with three catgut sutures. It is well, after the ring

is finished, to turn it inside out, so that the suture-knots shall be on the inside.

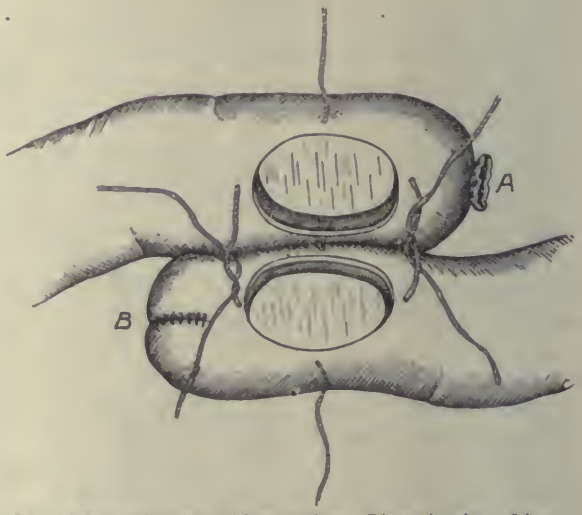
The main object in the after-treatment is to keep the patient as quiet as possible and to avoid unnecessary disturbance either with food or drugs.

In describing the operations on the hollow viscera we will go into the details of only lateral approximation of the ileum with or without resection, and of end-to-end invagination and implantation of the ileum into the colon, as all other procedures are based upon these and are simply variations. For instance, the approximations of the duodenum and stomach are performed by almost exactly the same method as an approximation of two loops of ileum. A short incision (two or three inches) is made through the abdominal wall. The parts to be operated upon are brought up through the incision and invariably so nearly fill the opening that it is unnecessary to take any other precautions to protect the peritoneal cavity from dirt; consequently, irrigation and drainage are unnecessary. During the operation the parts are frequently deluged with large quantities of warm water.

Simple lateral approximation.—A loop of the small intestine is grasped with the fingers and brought through the opening. The gut is quickly stripped between the fingers until about eight or ten inches are free from fæces. A rubber ligature is then placed at each end of the cleared space and lightly tied with a single knot. Of course, these ligatures must perforate the mesentery. This is accomplished by grasping one end of the ligature by a pair of hæmostatic forceps, carefully avoiding bloodvessels; it is then passed through the mesentery close to the gut. The incision is now made on the free surface of the gut directly opposite its mesenteric attachment, and the ring introduced. The opening is made as large as the ring will permit; it may, however, be enlarged after the sutures are introduced. As soon as the ring is in position the ligatures are passed through all the coats of the gut from within outward, the needles removed, and the ends allowed to hang loose until the other ring is in place. The end of the gut near the second rubber ligature is now treated in the same manner, and the second ring introduced. The corresponding ends of the opposite ligatures are taken up and tied together, thus completing the operation. To strengthen further the approximation a supplementary suture should in all cases be placed entirely around it, on the serous surfaces. We prefer a continuous silk suture for this purpose, as it gives a better and safer apposition, but it should include only the serous coat of the intestine. After this step is completed, the rubber ligatures are removed and the field of operation is thoroughly cleansed with warm water; the intestines are then carefully replaced in the abdomen and the abdominal wound closed. Silk sutures are used throughout this operation.

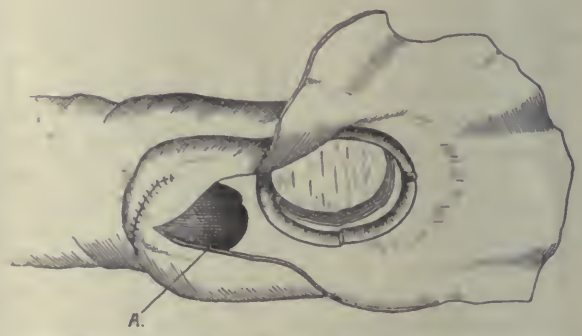
Lateral approximation with resection—In this operation the same steps are taken as in the preceding, with some additions. A larger section of gut is emptied of fæces, and, after the rubber ligatures are adjusted, as much of the intestine is resected as is desired. Care is taken to leave sufficient gut (three or four inches) beyond each rubber ligature, in order to have room to invaginate the ends and introduce the rings. When the mesentery is reached in making the resection, the mesenteric vessels should be grasped on each side by a pair of hæmostatic forceps. The incision through the mesentery is carried on each side along the line of the mesenteric vessels to a single point at the base of its attachment; it is

FIG. 2.



Lateral approximation with resection. Rings *in situ*. Ligatures ready to tie. *A*. Cut end ligated; *B*. Cut end invaginated.

FIG. 3.



Approximation completed. Section of gut opened to show ring in place. *A*. Invaginated end.

here ligated and cut away, thus removing a wedge-shaped piece.

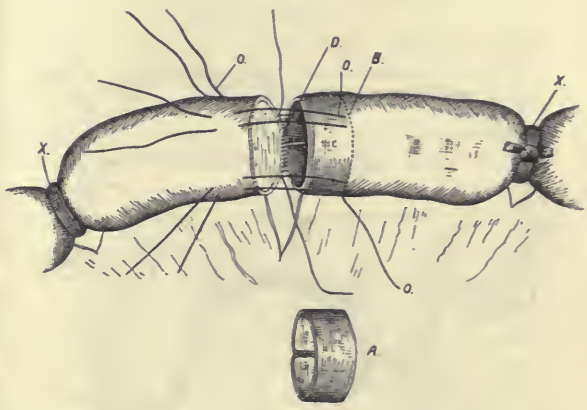
The next step is to invaginate the free ends of the intestine (Fig. 2). This is accomplished by first removing the hæmostatic forceps from one end and

then grasping the cut edge of the gut with the invagination forceps, care being taken to include at least half an inch of the bowel; the free end is now pushed into the gut, carrying the mesentery with it. A continuous suture is "whipped" over this inverted end, beginning at the mesenteric attachment and including this point; the forceps are then withdrawn. When the invagination is completed the bleeding from the mesenteric artery ceases. The second free end is treated in the same manner. From this stage the operation resolves itself into a simple lateral approximation, and is performed in exactly the same manner. Silk sutures are used throughout this operation. (Fig. 3.)

End-to-end invagination.—The first step in this operation is to make a resection. This is performed precisely as previously described. A rubber ring, of the proper size, is then introduced into the proximal end of the gut. The proximal end is found by sprinkling a few grains of common salt on the loop of intestine and watching the peristaltic wave which is excited. With a continuous catgut suture the cut edge of the bowel is stitched to the lower edge of the rubber ring. This holds the ring in place and prevents the complication of the ring slipping out or of the ends of the intestine curling.

A strong catgut suture with a needle at each end is now introduced. Each needle is carried in turn into the lumen of the gut until it reaches the upper edge of the rubber ring; it is then made to perforate the rubber, passing directly through both it and the intestinal wall. By this manœuvre both ends of the suture are brought outside of the gut. The gut-wall and upper edge of the ring are thus caught in the loop of the suture. One of the sutures is placed close to the mesenteric attachment of the gut, and the two are placed at equal distances from it and from each other. The operator now takes up two needles of the same ligature and introduces them into the distal end of the gut. The two ends of the suture should be placed side by side, and should run parallel with the long axis of the gut. They should perforate the tissues of the distal end half an inch above the cut edge, should pass through the peritoneal and muscular coats only, and should be brought out about one-fourth of an inch from their insertion. The other two double sutures are placed in a similar manner and the needles removed. That portion of the gut containing the ring is now invaginated into the distal end, the mesentery being carried with it. All the sutures are then pulled taut, but before tying them care must be taken to turn in, around the whole circumference of the intestine, the cut-edge of the distal end. A supplementary suture should be placed around the whole circumference of the invagination. For this we prefer a continuous silk suture. We have found that the operation can be more quickly and easily performed, and that it is safer if we rapidly stitch together the cut ends of the gut with a continuous suture passing completely through all the coats of the gut. This suture should be introduced just before the time of invaginating and tying the double sutures. No one has as yet brought this fact forward, and we believe that it will lessen the mortality to a great extent. The invagination is absolutely perfect, and with the final, supplementary suture there is a minimum danger of leaking. (Fig. 4.)

FIG. 4.

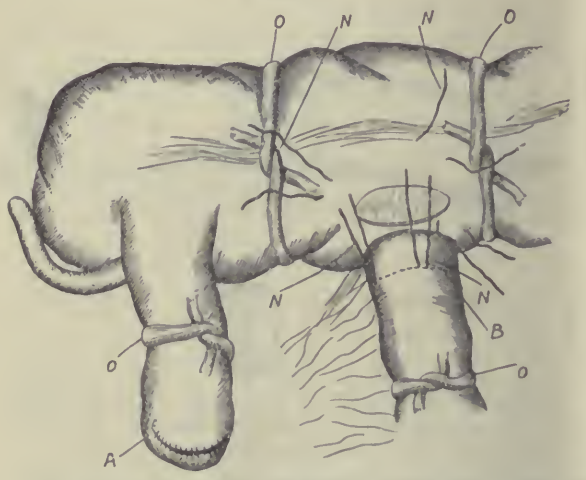


End-to-end invagination. *A.* Invagination ring; *B.* Upper end of ring when in place; *D.* Ends partly stitched; *OOO.* Ligatures in place; *XX.* Rubber bands in place.

Implantation of the ileum into the colon.—This procedure consists essentially of two operations, namely, a resection and an invagination. First, the ileum is resected in the usual manner, care being taken to invaginate only the proximal end of the severed gut. The resection should be made as close to the colon as possible, so as to leave only a shallow blind pouch. The colon is then brought into the incision and a portion (four or five inches long) immediately above the ileo-cæcal valve stripped free from fæcal matter; the fæces are held back by an extra pair of rubber ligatures, introduced and tied in exactly the same manner as described in the approximation and resection operations. A ring (similar to the one used in the end-to-end invagination) is placed in the free (distal) end of the ileum and is fastened there in the same manner as is the ring in end-to-end invagination; three sutures are also introduced as in that operation. An opening, large enough to admit the end of the ileum containing the ring, is made in the colon at a point directly opposite the attachment of the meso-colon. The sutures from the ileum are then introduced into the colon in the same manner as they are in the distal end of the ileum in the end-to-end invagination, only instead

of being passed in the long axis of the gut they are here passed so that they radiate in different directions in the transverse axis. The necessity of this arrangement of the sutures will be at once apparent when the parts are in place. The sutures being properly introduced, the ileum, carrying with it the mesentery, is invaginated into the opening in the colon. The sutures are then drawn taut and securely tied, care being taken that the cut-edges of the colon are inverted around the circumference of the opening. A supplementary continuous suture of silk should be introduced as in the other operations. (Fig. 5.)

FIG. 5.



Resection of ileum, with invagination of ileum into colon. *A* Resected and invaginated end of ileum; *B*. Upper end of invagination ring; *NNNN*. Ligatures in place; *OOOO*. Rubber bands.

We have conducted a large number of experiments on dogs during a period of some months, in order to familiarize ourselves with the technique of the operations, and to determine the safety of the several proposed operative procedures. The outcome of this experience has convinced us firmly that no one can do justice to his patients, should he be called upon to perform such operations without having previously done some experimental work, either on living animals or on the cadaver. The advantages of the living animal over the cadaver for such purposes are so obvious as to need no discussion.

In a large majority of the experiments we found that the omentum became adherent to the incision. This same condition is often found by those of us who are called upon to perform secondary operations upon the human subject. In post-mortem examinations we frequently noted that in cases in which during the operation no care had been taken to bring the omentum down, there were no omental adhesions. This was not only true as regards the incision but also the seat of the anastomosis. The question, therefore, naturally arises whether it would not be well in all cases of abdominal section to push the omentum up out of the way before closing the wound. It may be argued that if the omentum is not brought down and interposed between the incision and the intestines, the latter will become adherent instead of the omentum. This, however, has not been our experience with either the lower animals or human subjects. The peristaltic action of the gut is sufficient to explain this difference.

As to the value of omental grafts we have our doubts. It is true, as Senn and others have claimed, that in some cases in which there is danger of leakage and consequent infection, an abscess may form, and the general peritoneal cavity be protected for a time by the graft. Such has also been our experience. But at the same time it is true that, in cases in which no omental graft was used we had an occasional abscess, which was just as surely shut off from the peritoneal cavity by the contiguous folds of intestine becoming adherent about the seat of infection. In either case the abscess would probably prove eventually fatal, if not relieved by operation. The disadvantages of the graft are so plain that we would not attempt to use it in the human subject, except under peculiar circumstances. The fewer cut surfaces left in the abdominal cavity the better, as each one is a point to which some near knuckle of intestine may attach itself. This is, to our minds, one of the greatest disadvantages of abdominal surgery, and it has been most forcibly brought to our attention in this experimental work on the intestines. We have had numerous opportuties to examine the condition of the parts at varying periods of time after operation. In almost every dog which died or which was killed, we found the seat of the operation bound up in a mass of adherent omentum and intestines. Sometimes so great were these adhesions that it required very careful search to discover just which knuckles of gut contained the approximation, and a number of times, in spite of the greatest care, we separated the approximated surfaces in our efforts to discover the seat of operation. Every unnecessary raw surface tends to complicate this condition, and for this reason alone we believe omental grafts should be abandoned. Our own operations were successful without them. If the omentum is brought down and attached about the seat of operation without cutting the graft free, it makes the mass only the more complicated. Robinson and others have reported cases in which a knuckle of intestine slipped under this kind of graft and became strangulated. In these adhesions there may be a great future danger to the patient. It occurred to us that perhaps some material might be found that could be smeared about the seat of the operation and protect the parts from adhesions until the inflammatory condition abated

sufficiently to make adhesions safe. We were not successful, however, in finding anything. Van Lennep tells us that iodoform collodion, as recommended by Stern, will prevent the adhesions, but it also prevents the union of the approximated surfaces. It is to be hoped that in the near future some reliable substitute may be found. Very frequently abdomens are opened to break up adhesions and relieve pain or obstruction caused by these adhesions. Why should not some of these patients on whom we do approximation operations succumb to this condition? That such will be the outcome in a certain proportion of cases we have no doubt.

Another factor which adds to the danger of future obstruction is the small size of the communication between the intestines. This opening is, of necessity, smaller than the calibre of the gut, and for this reason alone there is danger of future trouble. As a matter of fact, the openings, as usually made, are smaller than necessary. This is the greatest fault with the Senn plate. Brokaw's and our own rings give the best chance for a free communication; there is a larger hole in the ring, and the narrow approximation surface takes up less of the much-needed room in the gut. Even with these rings we have found the resulting communications in the intestines too small. The openings have a tendency to become even smaller as healing and contraction go on. We have found in a certain number of cases large masses of fæces forming an obstruction immediately above the communication—one or two dogs dying from this cause. How, with these small openings and the masses of adherent intestines, all patients can escape future trouble from the operation itself we cannot see. Of course, we do not mean to decry the advisability of these operations. Every surgeon should be prepared and able to do them. In cases in which they are advisable it is, as a rule, a matter of life and death to the patient. If we saved a life for only a few weeks or months, the operation would be well worth the doing. We desire only to call attention to possible future dangers, with a view to discerning some way of preventing them.

There has been some discussion amongst operators as to the best method of bringing the two loops of gut together after resection. We have found it immaterial whether the ends of the gut be brought together side by side in the direct line of its long axis, or whether the two ends be folded on themselves. In either case the mesentery may be stitched together by a few extra sutures, if the operator prefers. It is probably safer to insert these extra sutures and thus avoid all danger of a knuckle of intestine slipping between two folds of mesentery. In case this accident should happen, there would be danger of subsequent obstruction. However, unless the hernia occurred within the first few hours after operation, adhesion would have taken place between the two mesenteric folds, and thus obviated the danger.

When a resection and a lateral anastomosis have been made, there may be several causes of trouble in the subsequent progress of the case, referable to the blind pouches left by the invagination of the free ends. In one of our cases the invaginated end was so long as to hang down over the communication between the intestines, and this acting as a ball-valve, caused death by obstruction. In other cases the *cul-de-sac* formed by the invagination was found filled with hardened fæces. Both these difficulties may be avoided by invaginating only a small portion of the gut, and then making the anastomosis-opening close to the end.

Together with all other operators, we have found that there is little danger of fæces accumulating in the portion of intestinal canal excluded by these operations. In all cases this portion of the gut has contracted, and has subsequently been found to be free from fæcal contents.

One of the most important lessons that our experimental work has taught us is, that the principle of *lateral approximation* should be used in every instance in which it can be applied. In itself it is a very simple and easy operation, and can generally be completed in from ten to fifteen minutes. In not a single case did we lose a dog on which we had performed a lateral approximation of two loops of the small intestine, with or without resection, except when we experimented with the cut ends after resection. Such has been to a great extent the experience of all operators. The principle of lateral approximation may be carried out almost *ad infinitum*. If two sections of the small intestine are to be joined, a lateral approximation should be made; if the small intestine and the stomach are to be brought together, the union should be by lateral approximation; if the small and large intestine are the parts to be dealt with, still a lateral approximation is the operation of choice: indeed, this method should be practised if any of the other hollow viscera are to be united. So thoroughly are we convinced of the greater safety of this operation over any of the other methods, that with our present experience we would not dare to attempt an end-to-end approximation or an invagination on the human subject in cases in which we had the choice. Our mortality from the end-to-end approximation after resection amounted to more than 30 per cent. Brokaw, in his experiments, had a mortality of 50 per cent., and other experimenters have shown no better results, whatever method was employed. The mortality of the implantation of the ileum into the colon after resection of the ileum just above the ileo-cæcal valve was better. Our first two or three operations of this kind ended fatally, because we used a faulty method,

and there was leakage. After we had learned how to do the operation properly, our mortality did not rise much above 10 per cent. Other surgeons have done better than this. Shimwell claims that all his operations of this kind terminated favorably. He is the only one, however, who has been so successful. The operation involves much greater handling of the parts, and it takes about twice as long a time to complete. In addition to this, it is a comparatively difficult operation to perform, and we have found it an unsafe one, even after long experience and with the greatest care. On the other hand, where we resected the ileum at the ileo-cæcal valve, and then made a lateral approximation to the colon higher up, we had uniform success, excepting in one or two instances, in which death was due to other influences. Shimwell found ileo-colostomy a very fatal operation, and believed it to be due to the tenesmic action of the colon. His ligatures broke in seven of these cases, all of which died. It is much more probable that he did not properly repair the damage done by the break (of this accident we will have more to say later) than that the operation was at fault. The mesocolon is long enough to permit sufficient peristaltic action without putting any strain on the approximated surfaces; at any rate, not more than occurs in the case of the approximation of the small intestine. In every case the colon must be brought out of the incision to make the approximation. If, therefore, it has sufficient freedom for this, it is free enough not to be subsequently injured by a little peristaltic action. When the colon can be easily brought into the wound (and if it cannot, the operation is practically impossible), the lateral approximation can be made as safely between colon and ileum, as between two loops of the ileum itself. Senn reported to the American Surgical Society at Washington two cases of lateral approximation of the colon and ileum done on the human subject, one of the cases making a good recovery.

In cases of lateral approximation with resection, it is necessary before approximating the two loops of gut, to deal with the open ends. The method adopted by all surgeons heretofore has been to invaginate the free ends and close them with a continuous suture. This detail occupies some time and the operation can be materially shortened if a more expeditious way were found of dealing with them. It occurred to us that a simple ligation of the end of the gut might answer the purpose, and this was tried in a number of cases (see Fig. 2, A). After a ligature was thrown around the intestine as near the cut edge as possible, the exposed mucous membrane was quickly scraped away with the handle of the scalpel, and the ends were freely washed with water, and dropped. This proved successful in a large proportion of cases—about 60 per cent. In the dogs which died, it was found that either quite a large end had been left, or the mucous membrane had not been scraped away with sufficient care. In all these cases there was a localized abscess about the stump, and in several a general peritonitis. As the matter now stands it would be an extremely unsafe procedure on the human subject. However, something may come of it in the future, and it is well worth the attention of experimenters. The stump is tied and dropped in this manner in cases of pyosalpinx and of diseased appendix vermiformis: Why not in the intestine itself? We would suggest that the ligature be applied, the stump carefully scraped free of mucous membrane (which can be readily done), the ends of the stump trimmed close to the ligature and a sponge saturated in an antiseptic solution held over it for a moment. It seems to us from our results that the method promises safety. Wherever there is sufficient material to invaginate, we would not think of attempting the ligation method, but cases may arise in which there is no tissue to lose and in such, if the latter can be done safely, it may prove invaluable. The point is well worth considering, and we hope to report further upon it.

The danger of breaking one of the approximation ligatures or of having it loosen during the manipulation, has been dwelt upon by several writers. Shimwell broke a ligature in eight different operations and lost seven of the animals. He asks, "What is the remedy?" and answers, "The only thing that can be done is to remove the portion of the ileum operated upon and to insert a new ring into the colon, being careful to pass the sutures well beyond the former sites." In our own work we broke a ligature three times, and in one case two of the four ligatures broke on account of a badly-prepared ring, and yet all the dogs made good recoveries. Lembert sutures were substituted at the points of break, care being taken to introduce them beyond the puncture of the broken ligature. We are at a loss to account for the bad results in Shimwell's operations, unless they were due to the rings. He used the Brokaw or rubber-tube ring, while we used our own solid rubber-cord ring. Our rings are so firm and do their work so well that after they are in place and two or three ligatures tied, the approximation is almost completed, and needs but little additional support. As we have proven in our work, it matters not if one of the ligatures breaks; the accident can be easily and quickly repaired by the insertion of a Lembert suture.

As to the necessity or even advisability of scarification, we decidedly take exception to the views advanced by other operators. The disadvantages and dangers of this detail in technique are, it seems to us, serious and its advantages *nil*. An uninjured

peritoneal surface will successfully resist infection, while one in which the solution of continuity has been broken will succumb. Consequently, if we scarify the peritoneal investment of the gut immediately around the openings, there is greater danger of infection, especially as that portion of this surface, not directly pressed upon by the rings, is practically free in the intestinal canal. This free scarified portion will, of necessity, become infected, and in case the approximation is weak at any point, even though it be not weak enough to allow of actual leakage into the peritoneal cavity, yet the adjacent scarified and approximated surfaces will be infected. In consequence of this, abscesses form between the approximated surfaces, and even on the sides of the approximation in the peritoneal cavity. Or, if the whole surface be infected, when the rings fall away, it will be found that union is weak or has not occurred. We have found these conditions in several cases in which scarification was used, but never when the approximation was made without it. Again, the bleeding almost always incident to the scarification considerably embarrasses the subsequent handling of the sutures and the completion of the final steps of the operation. If there were any advantages in the scarification these risks would be justified, but there are none. In no instance did an approximation fail where we did not scarify. The rings always remain in place for from four days to a week, and by that time the union of the unscarified peritoneal surfaces is sufficiently firm to resist any pressure likely to be brought to bear on them from within.

TREATMENT OF BLADDER DIFFICULTIES IN OLD MEN.[1]

BY JAMES A. JACKSON, M.D.,
OF MADISON, WISCONSIN.

THE general surgeon may profitably arrange the numerous subjects within his province into groups, classified in conformity with pathological, physiological, or anatomical relations.

Affections of the bladder are no exception, but should be considered from a standpoint which views the genito-urinary system as a whole, beginning with the meatus and ending with the kidneys, having always an eye to the interdependence and functional and structural relations between the various parts during health, as well as to their mutual influences when diseased. Anything, however, like an exposition of the pathology, diagnosis, and treatment of all the abnormal conditions of the bladder, or even of the diseases of this organ in old men, would far exceed the limits of such an article as this, it being my purpose merely to make a few suggestions which I hope will be of use in the management of these cases.

The proper action of the urinary system requires a normal condition of all its parts. If any one part be deranged, congenitally or by acquisition, the effect may sooner or later be felt throughout. The kidneys must be sound in function and structure, the pelves and ureters free and unobstructed; the bladder must be adequate as a convenient receptacle, with intact sphincter and detrusor muscles permitting periodical evacuations in a healthy manner; the prostate gland must be devoid of inflammation or hypertrophy, the circular muscles of the deep urethra exempt from spasm, and the calibre of the urethra, from meatus to bladder, must be up to the normal standard, and free from stricture.

It should be remembered that, although the pathological or mechanical conditions leading thereto may be numerous and varied, the end is practically the same—retention of urine, which unrelieved is followed by a typhoid, comatose state, terminating in death from "septo-uræmia," the result of absorption of ptomaïnes and non-elimination of urea. Hence, it is to the postponement or prevention of this final stage that all our efforts should be directed. Many patients have had more or less trouble for some time before applying for treatment, frequent and difficult micturition being the usual complaint, and assistance is not infrequently deferred until retention results, and the case has become complicated by consecutive pathological states of these organs.

Our ability to diagnose the exact condition will depend upon our familiarity with the numerous abnormal states of the urinary apparatus, and our skill in physical exploration; and it is equally true that our success in treatment will be in proportion to our recognition of the true causes, together with a judicious application of the most appropriate remedies.

We all have been taught to regard the prostate gland as answerable for most of these evils in old men, but if many preëxisting conditions had been earlier detected and properly treated, this gland would have escaped so much notoriety. This organ may, indeed, be the seat of the main difficulty, even though unrevealed by rectal examination. Therefore, we should not be satisfied with an investigation of this part only, but thoroughly inquire as to the condition of all parts of the genito-urinary tract.

Whenever, then, an old man complains of frequency or difficulty in micturition, or that he has to get up during the night to pass his urine, subject him to a careful examination to learn the cause of his trouble, be this a phimosis, small meatus, diminished size of the urethral canal, impacted calculus,

[1] Read before the Central Wisconsin Medical Society.

enlarged prostate gland, a diseased state of the bladder, a tumor or stone therein, or whatever else may be the probable or possible origin of the disturbance; and regard his kidneys as being in a more than doubtful condition; also do not forget that frequent micturition is often due to the overflow of a greatly-distended bladder.

Many of these cases have now begun their "catheter life," during which, unless otherwise relieved, the urine must be withdrawn once or more daily. Consider these people as always in a precarious state, for aside from risk of sudden retention, their kidneys may, at any moment, become badly deranged. These organs may suffer sudden congestion by reason of reflex influences, as in the so-called "urinary" or "catheter" fever; a nephritis, if already present, may become acute, or this disease may now for the first time appear; or, lastly, the renal organs are sooner or later liable to that form of suppurative inflammation from extension of septic processes from below upward known as "surgical kidney"; which name, rightly interpreted, means that the lower urinary tract has too often failed to receive the proper surgical treatment.

Look well to the patients' hygiene. Impress upon them the belief that their lease of life and freedom from complications will be proportionate to the care they exercise in regard to their daily habits of life. Avoidance of exposure during inclement weather is imperatively demanded; the labor of the kidneys is lessened when the skin is warm, but if unduly chilled, renal congestion and inflammation are very probable consequences, and for this reason the clothing should be sufficient to guard the surface from sudden or prolonged cold. The amount of exercise should be carefully regulated, overwork followed by fatigue with diminution of heat should be avoided, as it is apt to throw an additional burden upon the kidneys.

Keep the bowels regular, using, if need be, some gentle laxative, for a loaded lower bowel tends to congestion of the pelvic viscera, adds to the obstruction, and may cause hæmorrhage from the prostatic venous plexus.

Excesses in eating, and especially the over-use of malt or spirituous beverages, are to be forbidden, because they lead to indigestion, and load the urine with irritating substances, thus intensifying any existing disease, and not infrequently cause sudden retention.

The general health should be maintained, and remedies that give tone to the vesical muscles are often indicated; atony and paralysis of these parts are not seldom the starting-point of the trouble, and they always aggravate any other associated disease. The balsamic and stimulating diuretics and such remedies as disinfect and improve the urinary passages are often valuable. The patients must be instructed to evacuate the bladder with punctilious regularity at the very onset of any symptom signalizing future danger, provided this act can be accomplished in a natural way, and the organ completely emptied. Straining efforts should be checked as far as possible, and urination rendered easier by a squatting or other advantageous posture, the residue being expelled by gentle pressure upon the perineum with the hand. So soon as micturition *per vias naturales* also ceases satisfactorily to fulfil its purpose, the aid of the catheter must be called in.

When the case assumes a certain gravity, with urination at night, chronic cystitis, decomposing and residual urine, atony of the walls, and a depressed *bas fond*, the patient should be instructed in the introduction of an aseptic soft catheter. Indeed, the sooner the patient is taught how to evacuate the bladder in the evening by this method the better, for left to itself the disease progresses and dilatation and sacculation, with destruction of mucous membrane, follow as the forerunners of retention and intra-renal pressure, which are but too often the beginning of the end.

The instruments used by the patient should be selected by the surgeon, and time is well spent in teaching him how to keep his hands, catheter, foreskin, and meatus perfectly clean and free from septic matter. All filthy lubricants should be discarded in favor of carbolized or iodoformized fluid vaseline.

Unless the patient receives timely aid of a curative character, or unless his disease prove not to be amenable thereto, the time finally arrives when we are called upon to alleviate the pains and dangers of a distended bladder. In our laudable desire to feel the satisfaction of having skilfully evacuated this organ, we should not forget that there are some important indications in addition to the mechanical relief afforded by catheterization. Watch closely the condition of the kidneys, and remember that no matter how brilliant one artistic manipulation of the catheter may be, the interests of the patient will be far better subserved by the prevention of evil beyond the reach of surgical art.

Antiseptic precautions are as requisite in this condition as they are elsewhere. When aseptic conditions already exist, antiseptics may seem out of place, and in many cases of sudden retention from hypertrophied prostate or spasm of the urethra, the bladder is comparatively free from disease, and contains an acid urine devoid of pathogenic microbes. Often we cannot be sure as to this, and it is far safer to adopt the antiseptic system in all cases.

This holds with still greater force whenever there is an accidental exposure of raw surface by means of any kind of instrument. Therefore, in order to avoid repetition, I would urge the necessity of

always making use of this method whenever we perform any kind of operation on these cases, from the simple introduction of an aseptic catheter to the perfect antiseptic technique of a suprapubic or perineal cystotomy. By so doing we not only save the patient from the dangers incident to septic invasion of these organs, but prevent the still greater one of suppurative nephritis. We should endeavor to prevent by all possible means the occurrence of any reflex irritation due to the passage of instruments, which irritation would cause chills, fever, and prostration in proportion to the renal disturbance. Never pass the catheter with the patient standing or in a cold room. Put him in a warm bed, give a dose of quinine or Dover's powder, or bromide with a hot drink, and, if convenient, a warm bath. This, or similar treatment, equalizes the circulation and lessens reflex excitability. Either a hard or a soft catheter may be used.

The cautious use of cocaine ought perhaps here to be considered, but if an anæsthetic be necessary or advisable, I would generally prefer pure chloroform carefully given as being the safer agent under these circumstances. Obviate the risk of congestion and hæmorrhage due to sudden relief of pressure, by withdrawing at first very slowly only part of the bladder contents, gradually increasing the quantity removed at each subsequent evacuation until the organ can be safely emptied. It is well to replace part of the withdrawn urine by the careful injection of a solution of one of the safe antiseptic agents, like boric acid. This liquid will also serve to flush the urethra, and later on for daily irrigation of the bladder when cystitis is present or probable.

If, after fairly-well conducted efforts with the catheter, failure to reach the bladder ensues, it is wise to abstain from further fruitless attempts, and rather than inflict additional injury, to resort to one of the other means for emptying the viscus, the simplest and best of which is suprapubic aspiration, and which, properly done, is quite safe and may be repeated a few times with the hope that the relief so obtained will result in restoration of natural micturition, or, at least, in admission, *per urethram*, of the catheter. Should, however, these hopes not be realized, and the urine be foul and purulent, with chronic cystitis a marked feature, even this measure should yield to one more effective in establishing drainage, permitting irrigation, and affording physiological rest to the parts. We can then choose either suprapubic or rectal puncture with a curved trocar, leaving the canula *in situ*. Harrison's method of "tunnelling the prostate," or Cock's operation of perineal puncture with a bistoury, either of these would meet with my approval.

Did time permit we would also discuss the indications for perineal cystotomy at a period when the urethra is yet permeable by a grooved sound, which operation in properly-selected cases, by affording rest and drainage to a distressed bladder, is capable of putting a stop to the disease.

AN EPIDEMIC OF TINEA TRICHOPHYTINA CRURIS.

BY HENRY W. STELWAGON, M.D.,

AND

B. FRANKLIN STAHL, M.D.,

OF PHILADELPHIA.

TINEA trichophytina cruris—tinea cruris, eczema marginatum, ringworm of the thighs—as met with in this country, may be briefly described as an eczema-like eruption, with a sharply-defined, red, elevated, sometimes papulo-vesicular or vesico-pustular border, involving the cruro-genital folds, the inner surfaces of the thighs and contiguous sides of the scrotum, and at times extending downward several inches, exceptionally invading the pubic and lower abdominal surface, and, in rare instances, the axillæ. The severe type of the disease, involving the greater part of the thighs, lower abdomen, scrotum, anal folds, inner portions of the buttocks, with marked thickening and infiltration persistently rebellious to treatment, is, fortunately, rarely met with outside of certain countries. The cases here to be referred to presented in their clinical symptoms, nothing unusual beyond their acuteness and epidemic character; in some respects the area of disease was, comparatively speaking, somewhat limited, but this was doubtless due to the short duration and to the fact that therapeutic measures were early adopted.

This epidemic occurred, two or three years ago, in the Philadelphia Hospital, chiefly among the resident medical staff, but later in its course involving several officials and two or three of the nurses of the training-school. It was first noted in one of the resident physicians in July, and for six or seven weeks was limited to this patient. From this time on, however, its spread among his *confrères* was rapid, and before the disease had disappeared eighteen of the staff, several of the other officials, and several nurses had been attacked. Those of light complexion exhibited the more pronounced types of the disease, and the two out of twenty resident physicians who escaped were brunettes. So far as could be learned, in not more than two of the nurses was the cruro-genital region affected, but in two or three others several ringworm patches developed on other parts. As remarked, in most of the cases the surface involved was not large, but in a few instances the disease extended several inches down the thighs. Moreover, in a few cases, the axillæ were, primarily or secondarily, invaded; and

in several of the subjects also, one or two typical ringworm patches presented at other points of the general surface, for instance on the face, feet, and limbs. In almost all of the cases, and in all of the patches, the degree of inflammatory action, although superficial with inconsiderable thickening or infiltration, was unusually severe from the beginning, precluding, as experience showed, the use of the stronger applications commonly employed in the treatment of this affection.

The cases came under our conjoint observation and care after the epidemic was well established. Several of the resident physicians had prescribed for themselves strong remedies with the hope of aborting or rapidly curing the disease, but with scarcely an exception, with the result of aggravating the symptoms and bringing about a painful, eczematous inflammation. With this fact brought to our notice it was thought, under the circumstances, advisable to use one of the milder parasiticides, and a lotion of sodium hyposulphite, a drachm to the ounce, was, therefore, prescribed. In cases just recovering from the effects of too strong applications, a carbolized boric-acid lotion, containing a few minims of glycerin and alcohol to the ounce, was employed at first, this subsequently giving place to the wash of sodium hyposulphite. Under the continuous employment of the latter remedy, the disease was gradually brought under control and in the course of several weeks—by the middle of November—was completely relieved. In all, the disease had attacked about twenty-five persons, and this within a space of several weeks. Later there was a slight recurrence in one or two of the patients, which, however, rapidly disappeared under a resumption of treatment. In the whole hospital, including officials, physicians, nurses, and inmates, excepting possibly two or three cases which, upon an average, were always present in the institution, no other cases and no tendency to its spread were to be noted.

The main interest of this group of cases naturally hinges upon their source and the method of contagion. The epidemic itself had, we believe, in all probability, its origin in the case of the first resident physician attacked, and who, it will be remembered, remained the sole one affected for almost two months. In his case the disease was doubtless contracted in some accidental manner, for it could scarcely be accepted that this case and those subsequently affected had a common origin, inasmuch as the others were not attacked for some weeks later, and then almost simultaneously. The method and means of its spread may have been thus: The soiled linen of the resident staff was washed in the laundry of the institution at the same time and in the same machines, and it seems probable that in this manner the spores and mycelium of the trichophyton from this first case, as soon as the fungus had developed in sufficient quantity to be an active source of contagion, found their way to the others. The linen of the other house officials and nurses attacked was washed in the same machines in which that of the physicians had been laundried, but on different days, and naturally the contagious elements remaining over in the machines, if present at all, would be in scant quantity; this fact would, we think, explain why so comparatively few of these officials, and probably only those especially susceptible, contracted the disease. That this is the correct explanation of this curious epidemic, however, we feel by no means certain, but after a careful and thorough examination into the facts and surroundings, it seems to be that which has the most plausible support.

ORIGINAL LECTURES.

DIGESTION, ASSIMILATION, AND OXIDATION—THEIR NORMAL AND ABNORMAL CONDITIONS IN RELATION TO HEALTH AND DISEASE.

A Series of Clinical Lectures delivered at the New York Post-Graduate Medical School and Hospital.

BY WILLIAM HENRY PORTER, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY.

LECTURE III.

GENTLEMEN: To-day I show you a case of ordinary but somewhat persistent subacute rheumatism and a case of diabetes mellitus, not because they can be classed as dyspeptics, but because I believe that each of these conditions arises in a disturbance of the digestive and oxidative functions of the body. Our first patient, Mr. E., "was perfectly well" until six weeks ago, when he developed a moderately severe attack of articular rheumatism. His left wrist became swollen and painful, and its motion somewhat impaired. In his case the symptoms have been confined to this one locality, and at times have been quite severe. He has been treated in various ways but without permanent benefit. His urine is scanty, high colored, and strongly acid. He is pale and anæmic. His tongue is slightly coated, pale, flabby, and deeply indented by the teeth, indicating a poor nutritive state. His previous habits have been fairly good, but he has lived largely upon a vegetable diet, and has been much exposed to wet and cold.

This case is interesting, not so much for its intensity, as for its persistence, and clearly illustrates the necessity of a prolonged course of constitutional treatment to improve the general nutritive condition of the body, if the rheumatism is to be cured and completely eradicated from the system.

My theory in regard to rheumatism is, that it is chiefly caused by an over-indulgence in starches, sugars, and fats, more of these CHO compounds being taken into the system than can be completely oxidized, and as a

result, instead of the complete products of their oxidation—carbon dioxide and water, incomplete substances are formed, the nature of which is not accurately understood. These imperfect elements of oxidation are called antecedent products to the complete formation of lactic acid, and are taken up from the blood by the epithelial cells lining the uriniferous tubules and discharged into the urine as completely-formed lactic acid. The oxidation of the proteids or CHNOS compounds is also imperfectly effected, which gives rise to the presence of uric acid and urates in the urine.

The chief disturbances, however, are in the metabolic changes of the starches, sugars, and fats. The incomplete oxidation and imperfect nutrition, and the increased work thrown upon the kidneys furnish the true explanation of the renal disturbances or Bright's disease, frequently associated with or occurring as sequelæ to rheumatic attacks. The physiological abnormality that produces the one is a potent factor in exciting the other, the degree and intensity of the attack determining the result obtained. This supra-acidity of the urine has given rise to the common expression of over-acidity of the system and blood, a convenient but inaccurate way of speaking. Over-acidity of the system is impossible, for lactic acid cannot exist and circulate in the blood, although we can have a decrease in the normal alkalinity of all the fluids of the body as the result of imperfect oxidation. The antecedent products of lactic acid are assumed to be in the blood and to act on the dense or white fibrillated connective-tissue structures of the body and by their presence to excite an excessive determination of blood to these structures, giving rise to the symptoms commonly known as rheumatic. The lesion produced may be a simple engorgement of the blood-vessels of the part causing pressure-effects, and secondarily the painful symptoms; or changes truly inflammatory in character may be developed which cause the local and constitutional manifestations. In the former condition the constitutional symptoms are slight, but in the latter they are often well marked, thus enabling us to differentiate between the two conditions.

In subacute cases like that of the patient before us, in the muscular forms, and in the mild attacks of the acute variety of rheumatism, I am inclined to believe that inflammation in its strict limitations does not enter into the pathological conditions, but that the rheumatic poison causes a marked and often prolonged afflux of blood to the part, followed by severe pressure-effects and a hyperæsthetic condition of the nerves, and in this way the painful symptoms are developed and maintained. If the engorgement is prolonged a supra-nutritive condition is produced, new tissue is formed, and permanent structural changes are induced until finally the condition known as chronic rheumatism, and without inflammation, is developed.

That the rheumatic infection is a general and constitutional poison, and in all cases acts locally rather than through the central nervous system, is clearly proved by its capriciousness, often developing suddenly in a joint- or intermuscular septum, remaining for a few hours or days in all its intensity and then disappearing almost as quickly as it appeared. The first attack may be the only one, but more frequently it reappears either in the locality first affected or in some more remote part of the body. This rapid appearance and disappearance is in opposition to a true inflammatory lesion, but indicates a congestive lesion, which can be quickly produced and as speedily dispersed. The results of treatment also point toward a congestive condition rather than an inflammatory lesion, as the only class of drugs which seem to give positive relief are the alkalies and those which depress the heart's action and lower the general blood-tension. For the acute rheumatic attacks nothing relieves so quickly and effectually as free mercurial purgation followed by salicylic acid or the salicylate of sodium. I prefer the following formula:

℞.—Salicylic acid . . . 3 drachms.
Sodium bicarbonate . . 2 . "
Elixir of gaultheria . . 1 ounce.
Glycerin . . . . ½ "
Water sufficient to make . 4 ounces.—M.

Dose, one fluidrachm every hour.

The salicylates should be given hourly until their full effects are produced, then the interval between the doses should be lengthened from two to three or more hours, as may be required.

By closely following the rules of diet and treatment about to be given in connection with digestive disturbances in general, these recurring attacks of rheumatism can be prevented and the rheumatic habit completely eradicated. Success in this line may require more patience and persistence than falls to the lot of the mass of humanity, but it can be accomplished if desired.

Our second case, Mr. W. A. S., aged forty-two years, a cigarmaker, "was well" until six years ago. From boyhood up to the time that he became noticeably sick he was in the habit of eating very heartily, in fact, as he states it, "enough for two or three ordinary persons." About six years ago he commenced to suffer from dull aching pain in the lumbar region, swelling of the feet and legs, epistaxis and marked cephalalgia. He also had some cough associated with pain in the chest. His mouth and throat have been and are now very dry, and he has great thirst. Early in his disease the quantity of urine that he passed was small, but during the last five years it has been abnormally large. At the present time he is passing from seventy to eighty ounces of urine daily. The urine is strongly acid, lemon-yellow in color, has a specific gravity of 1030, and contains a large quantity of glucose and some albumin. The urea is decreased in quantity, while the uric acid is increased. There are marked periosteal tenderness and perceptible emaciation. He also complains of dyspnœa, anorexia, troublesome itching over the whole body, and marked constipation. Physical examination of the chest reveals the evidences of a moderate amount of chronic interstitial pneumonia, and a weak and feebly-acting heart. This is clearly a long standing case of diabetes mellitus.

My theory in regard to diabetes mellitus is that it is chiefly due to over-feeding, as is well illustrated in our patient. In fact all persons, from a physiological standpoint, are gormandizers, some to a greater extent than others. Some can stand the strain better and longer than others, because their inherent vitality is greater. Those who reach the maximum degree of over-feeding are especially liable to develop the uric-acid, the gouty, or diabetic condition, especially the latter.

TABLE I.

POSSIBLE PRODUCTS OF OXIDATION OF THE PROTEIDS OR **CHNOS** COMPOUNDS.

	Proteids +	*Amt. of O. Used* =	*Urea* +	*Uric Acid* +	*Kreatinine* +	*Glucose* +	*Carbon Dioxide* +	*Water* +	*Sulphuric Acid.*
1. Highest oxidation	$C_{72}H_{112}N_{18}O_{22}S$. +	154 O =	$9(CH_4N_2O)$	.....	.....	.....	$63(CO_2)$ +	$37(H_2O)$ +	H_2SO_4
2. Supra- "		152 O =	$7(CH_4N_2O)$ +	$(C_5H_4N_4O_3)$	.....	.....	$60(CO_2)$ +	$39(H_2O)$ +	H_2SO_4
3. Normal "		139 O =	$4(CH_4N_2O)$ +	$(C_5H_4N_4O_3)$ +	$2(C_4H_7N_3O)$	.....	$55(CO_2)$ +	$38(H_2O)$ +	H_2SO_4.
4 Sub- "		136 O =	$2(CH_4N_2O)$ +	$2(C_5H_4N_4O_3)$ +	$2(C_4H_7N_3O)$	.....	$52(CO_2)$ +	$40(H_2O)$ +	H_2SO_4.
5. Lowest "		76 O =	$2(CH_4N_2O)$ +	$2(C_5H_4N_4O_3)$ +	$2(C_4H_7N_3O)$ +	$5(C_6H_{12}O_6)$ +	$22(CO_2)$ +	$16(H_2O)$ +	H_2SO_4.

The foregoing table, which has been worked out in this connection, shows at a glance how incomplete oxidation of the proteids will yield either the uric-acid or diabetic condition. You also see by reference to the following table (Table II.) how much more oxygen is required to oxidize one molecule of starch, sugar, or fat than is demanded to satisfy one of a proteid nature.

TABLE II.

PRODUCTS OF OXIDATION OF THE **CHO** FOOD STUFFS.

Starch,	$C_6H_{10}O_5$	+ 12 O =	$6(CO_2)$	$5(H_2O)$.
Sugar,	$C_6H_{12}O_6$	+ 12 O =	$6(CO_2)$	$6(H_2O)$.
Palmitin,	$C_{51}H_{98}O_6$	+ 140 O =	$51(CO_2)$	$44(H_2O)$.
Olein,	$C_{57}H_{104}O_6$	+ 160 O =	$57(CO_2)$	$52(H_2O)$.
Stearin,	$C_{57}H_{110}O_6$	+ 163 O =	$57(CO_2)$	$55(H_2O)$
Total,	$C_{177}H_{334}O_{29}$	+ 487 O =	$177(CO_2)$	$16.(H_2O)$.

Thus we see that if we eat twice as much as can be oxygenated in the blood, and especially if the CHO compounds predominate, general body-oxidation must be imperfectly performed. As the starch, sugar, and fats are more easily oxidized, and require such a large amount of oxygen, they act as the chief factors in preventing the complete oxidation of the proteid compounds. After this supra-feeding and incomplete oxidation have been continued for a certain length of time the protoplasmic vitality of the hepatic cells is affected, and, as a necessary sequence, the bile-secreting and excreting powers of the liver are still more decreased, in fact, all the functions of the liver are seriously deteriorated. The digestive functions become more positively disturbed, oxidation perceptibly affected, and the emaciation progressive and marked. The work imposed upon the kidneys is now greatly increased and their nutrition impaired, and, as a result, the renal cells, like the hepatic, undergo marked swelling and granular metamorphosis, and constitute, with the primary degeneration of the hepatic cells, the only constant and uniform lesion in diabetes mellitus. The sequel of this imperfect action on the part of the liver and oxygenating function of the system is the development of an abnormally large number of incomplete products of tissue-waste. These finally reach the kidneys and are excreted with the urine, chiefly as crystalline uric acid, glucose or albumin. Sometimes only one of these products will be found in the urine, at other times all three will be noted in the same sample, as is the case in our patient of to-day. The milder forms of disturbed oxidation[1] will result in the formation of uric acid only, more severe cases[2] develop in addition glucose. Others may have also derived albumin[1] and various by-products, all resulting from the incomplete oxidation of the proteids.

Viewed in this light the best food for a diabetic patient is a well-regulated mixed diet, which is limited in quantity and relatively small in the CHO elements. To prohibit the latter completely, as was at one time customary, does more harm than good. Let the quality of food be good, the quantity small, oxidation as nearly complete as possible, and then nutrition will be raised to the highest attainable standard, and protoplasmic vitality improved or completely restored. If this result is obtained the diseased condition, theoretically speaking, ought to be entirely eradicated from the system. The principal reason why this is not more frequently accomplished practically, is because the glandular epithelium throughout the body has become so much deteriorated, and the vital nutritive activity is at such a low ebb before the condition is recognized and treatment instituted, that the inherent power of the system is not sufficient to repair the damage and sustain the vital functions at the same time, even though the digestion and oxidizing powers of the body are placed in the most favorable condition.

Before commencing the discussion on the treatment of cases with a disturbed digestive function, it may be well to glance for a moment at the Tables which I have here for your inspection. First, let us look at the CHO compounds (Table II.), which are the most easily oxidized. If we consider the whole group together we find that it requires 487 atoms of oxygen to satisfy one molecule of the CHO group.

TABLE III.

RESULTS OF OXIDIZING **CHO** COMPOUNDS.

Starches, sugars, and fats	yield to the body	Heat, energy, and rotundity, and act as lubricating agents,	and are excreted from the body as	Carbon dioxide and water.

We find by referring to Table III. that the oxidation of the starches, sugars, and fats yields to the system heat, energy, rotundity, and lubrication, but without the development of any tissue-nutrition, or muscular or glandular activity. The waste of oxygen, however, is not so great if we deal with the starches and sugars alone; but when the relative proportions of the CHNOS to CHO compounds in the animal and vegetable food-stuffs are considered (Table VI.) we find an enormous preponderance of the CHO elements over the proteids. Remembering how easily the CHO elements are oxidized, and

[1] Table I., line 4. [2] Table I., line 5.

[1] The Post-Graduate Journal, p. 13, January, 1891.

that the digestion and oxidation of a vegetable albumin at best is a far more difficult task than is the oxidation of an animal proteid, I think you all can readily appreciate how eating too abundantly of the vegetable food-stuffs is very apt to overtax the oxygenating capacity of the system. Having to depend as we do upon the proteids or CHNOS elements for the development of tissue, muscular and glandular activity, and some of the bodily heat and energy (Table IV.), it is absolutely essential that we should maintain perfect oxidation of the proteids if the highest nutrition is to be sustained and the greatest working-power developed.

TABLE IV.

RESULTS OF OXIDIZING **CHNOS** COMPOUNDS.

The proteids $C_{72}H_{112}N_{18}O_{22}S$ { are developed into all forms of bodily tissue } yielding { Heat, energy, muscular and glandular activity, } = and are excreted from the body as { Urea, uric acid, kreatinine, carbon dioxide, water, and sulphuric acid.

Let me refer to the following Table, which shows the relative proportions between the CHNOS and CHO compounds from a diet barely sufficient to maintain life to that demanded by forced labor.

TABLE V.

COMPARATIVE DIET TABLE.

Diet	CHNOS	CHO
Bare subsistence	100	100
Moderate exercise	180	161
Active labor	232	171
Forced work	242	189

We see that the increase in quantity is found to be greater in the case of the proteids than in the simple CHO elements, consequently the demand cannot be satisfied with a purely vegetable diet, without great danger of overtaxing the oxygenating capacity of the system and thus exciting conditions of disease. Of course, a few isolated cases can always be found of individuals who have seemed to accomplish the result upon a purely vegetable diet; but both theoretically and practically it cannot be done by the great mass of humanity. The inherent vitality of a few persons is very great and their oxygenating capacity unusually large, so much so that they seem to disprove completely the common rule. A close clinical study, however, of the habits of humanity at large, and experimental work carried out among soldiers and prison laborers, in whom the diet is accurately known and regulated, conclusively proves that there is marked deterioration of both physical and mental vitality if an exclusive vegetable diet is used. Among pure vegetarians the infant mortality is also very large and tuberculosis quite prevalent, the reverse being true if an animal or proteid diet is administered.

A mixed diet, well regulated as regards both quantity and quality, will unquestionably yield the most satisfactory results so far as perfect nutrition and working capacity of the system are concerned.

TABLE VI.

COMPARATIVE COMPOSITION OF FOOD-STUFFS.

	Water, H_2O.	Proteids, CHNOS	Starch, Sugar, and Cellulose, CHO.	Fat, CHO.	Salts.
Milk { Human	88.91	3 46	4.62	3 48	0.21
Milk { Cow's	86.23	3.73	4 93	4 50	0.6
Eggs	65.0	18 2	.....	15.3	1.0
Beef	77.5	16.0	.....	5 0	1 5
Beans	9 9	25.5	60 6	2.8	3 2
Peas	9 9	20.2	63.9	2.0	3.0

Rice	.....	7.55	90 75	0.80	0 90

In the foregoing table of food-stuffs we find that milk, the first food of the infant, contains a large percentage of CHO elements, but as the period of lactation progresses these CHO compounds gradually decrease. This large percentage of CHO elements is unquestionably intended to yield heat and energy to the growing tissues of the child, until they have developed sufficient vitality and inherent activity to be a source of heat and energy to themselves. Then, with the development of the teeth and the almost incessant motion of the growing infant, milk does not seem to be sufficient to satisfy the nutritive demands of the system, and eggs, meat, and the more highly nutritious foods are demanded if the highest physical and mental powers are to be developed. Too frequently, however, the CHO elements are increased at the expense of the CHNOS compounds; fat, soft, and plump babies are developed, false habits of feeding engendered, nutritive vitality is sapped, and a foundation laid for the entrance into the system of all kinds of disease, especially the tubercular infection. The proteid-fed baby is never very fat, but its limbs and muscles are plump and firm and its resisting power against disease is at the highest standard, in fact, it is not likely to contract disease of any kind, even if brought in contact tact with those of an infectious or contagious nature.

Taking this view of the subject, together with a clinical, careful, and personal study of hundreds of cases, I have come to the conclusion that imperfect diet, digestion, oxidation, and assimilation are the source of a large percentage of our chronic diseases. They are the foundation, as it were, in the development of all disease-processes, both acute and chronic. To be successful in the treatment of disease we must thoroughly understand this subject and apply our medicinal agents, not so much with a view to relieving the symptoms presented, but toward correcting the abnormal physiological conditions which are producing pathological processes. So soon as we are able to interpret the incipient manifestations correctly, we can at once go back to the primary source of the trouble, anticipate symptoms and effect cures before the more serious changes have had time to develop.

What I am about to say in connection with the so-called dyspeptic affections, applies with equal force to all disease-processes. Over-feeding, both in health and in disease, has, without doubt, been the cause of many an untimely death; and there is now a growing tendency to feed less and to oxidize what is taken more completely, Knowing that over-feeding causes incomplete oxidation and malnutrition, and that it is the potent cause of the intestinal and hepatic character of disease, we are placed in a position to treat these maladies rationally.

Having already found by our study of the physiological process of digestion, that the major part of the work is accomplished in the intestines and by the liver, we can easily rule out the stomach as being primarily at fault in a large majority of the cases presented for treatment.

From these observations, it is reasonable to suppose that in but few cases are dyspeptic symptoms to be interpreted as originating in the stomach, although, generally speaking, they have been so regarded and treated, with an almost universal history of failure so far as satisfactory and permanent relief is concerned. If we carefully analyze those cases that present symptoms directly referable to the stomach, we find, as well illustrated by our patient of last week and by hundreds of other cases that have come to this clinic for treatment, that behind them all, there is more or less intestinal and hepatic derangement, which must be removed before a perfect and permanent cure can be effected.

When the stomach is primarily and chiefly at fault, the diagnostic symptoms are marked discomfort and pain while taking food or immediately afterward, followed quickly by the belching up of acid or alkaline gases or fluids, associated with or followed by vomiting. So soon as the stomach is emptied, relief is afforded. Certain kinds of food-stuffs will aggravate this condition, while others will be well borne.

When the disturbance is intestinal and hepatic in character, there is no distress or pain at the time of taking food, and the stomach seems to tolerate all varieties of food equally well. But after the meal, the abdomen commences to swell, the clothing feels too tight, and tympanites and boborygmi are developed to a marked degree, the latter often keeping the patient awake at night. With the abdominal distention there is often uneasiness or even acute pain in the *scrobiculus cordis*, which may be so great as to cause nausea, vomiting, and faintness, or lead to the suspicion of the existence of malignant disease of the stomach, or of an aneurism of the abdominal aorta. This symptom is due to the transverse colon being abnormally distended and wedged upward and backward between the stomach and the vertebral column, which causes the solar plexus to be more or less severely compressed. Over-distention of the stomach without general tympanites, as a rule, does not compress the solar plexus and cause pain, whereas over-distention of the colon almost invariably does. After the distress and pain have lasted for a number of hours, the patient obtains relief by belching up the gas which has been accumulating in the large intestine—this accumulated gas having been forced back into the small intestine and stomach by the peristaltic action being reversed — or the gas may be passed *per anum*. The latter is the exception, for these cases are usually obstinately constipated. The intestinal and hepatic cases usually have a dirty, muddy-looking skin, and are chronically semi-jaundiced. They pass scanty, high-colored, dense and acid urine, which often contains a large quantity of uric acid, urates and oxalates, and an abnormally small quantity of urea. The headache, vertigo, and various vague and neurasthenic symptoms indicate a condition involving the intestinal and hepatic functions rather than the stomach alone.

By a close study of a large number of these cases, I have beeome firmly convinced that a pure and simple stomach dyspepsia is exceedingly rare, if not almost an impossibility, while the hepatic and intestinal cases are daily seen by every practitioner. Treatment directed to the stomach relieves only temporarily at best, while attention to the intestines and liver will cure the most severe and confirmed dyspeptic.

In the class of gastric cases in which there is a hypersecretion of gastric juice or of its acid, the acute symptoms can be relieved by administering bicarbonate of sodium after each meal; this quickly neutralizes the over-acidity and tends to improve temporarily the general condition. Or the hypersecretion can be arrested by giving an acid before meals, which tends to decrease the secretion from the gastric membrane. Nitro-hydrochloric acid is the best form of acid to administer, as it improves the functional derangement of the liver, which is often a predisposing cause of the gastric symptoms. If we assume, however, that this gastric acid dyspepsia is due to a deficiency in the primary flow of the acid gastric juice and that the supra-acid condition is to be attributed to the lactic-acid ferment decomposing the saccharine elements and thus producing the acidity, then a different line of treatment must be instituted. If the bicarbonate of sodium is given for temporary relief, it tends to neutralize completely the acidity of the gastric juice and destroys gastric digestion, throwing the entire work upon the intestinal tract; in fact, all the alkalies seem to do but little good. The nitro-hydrochloric acid here again holds the first place among our list of remedial agents, but it should be administered after the meal with a view to converting the albumin in the stomach into syntonin, thus favoring the digestion of the proteids by the pepsin present. This together with the favorable influence of the acid upon the hepatic functions will improve the nutritive functions in general, and finally restore the gastric secreting membrane to a normal condition. These physiological differences must be recognized and appreciated if the most effective line of treatment is to be instituted.

The alkaline form of gastric dyspepsia is usually due to a deficiency of the primary flow of the gastric secretion, and is secondary to fermentative changes. This condition, like the former, can be both temporarily and permanently relieved by the administration of nitro-hydrochloric acid after meals. To give these cases pepsin, bismuth, and a host of other drugs, is simply a waste of time for the patient and ultimately discreditable to the physician.

This brings us to the most interesting part of our subject, namely, the management of intestinal and hepatic indigestion with general physiological impairment of all the functions of the body. The treatment of this

somewhat complex subject is best divided into two parts, the dietetic and medicinal.

Assuming that the condition of disease is due to overfeeding and incomplete oxidation, the first step is to remove the cause by cutting down the amount of food taken and to improve oxidation by exercise in the open air. My rule is, at first, to cut off as nearly as possible, all the CHO food-stuffs, and place the patient upon an almost exclusive proteid or CHNOS diet. This is best accomplished by limiting the food to from four to six ounces of skimmed milk or buttermilk every two or three hours, as may be required to satisfy the demands of hunger or faintness, or by an exclusive diet of matzoön.[1] In this way the CHO compounds are, to a large extent, excluded from the system, and all the oxygenating capacity of the body is brought to bear upon the proteid or CHNOS compounds or the truly nutritive elements. As a result of this line of action, oxidation of the proteids is forced up to a higher point than the normal standard, and the highest nutritive and reparative action is developed with the least expenditure of vital force. The amount of effete material to be eliminated from the system by the excretory organs is largely reduced, for by this more complete oxidation we get the simplest and smallest number of excretory products and those which are easy to eliminate, namely, urea, carbon dioxide, and water.

This is clearly illustrated in our first table (Table I., line 1), which shows the possible products of oxidation of a proteid body. This plan of feeding is continued for from three to six weeks, at the end of which time an almost insatiable craving for solid food is usually developed. This, in connection with the improved condition of the urine, is an indication that the nutritive vitality of the protoplasmic elements of the body has been improved, if not absolutely restored to its normal state, and that the system can stand a more varied diet. Eggs may next be added to the milk, and finally a little stale bread, with all kinds of lean meat, including beef, mutton, and fowls, as well as fish, oysters, clams, etc. Maccaroni can be substituted for vegetables, not because it is a CHO substance, but because it is chiefly composed of the proteid elements of the grain separated from the starch and sugars. It is best cooked by first boiling for two hours or until it is soft and jelly-like, then adding a little milk and cheese and baking. In this form it is a strongly nitrogenous food, but satisfies the cravings for a vegetable. By following this line of feeding, nutritive vitality will be restored, health reëstablished and the patient finally brought back to a well-regulated and mixed diet. The excessive use of the CHO compounds, and especially potatoes, should be scrupulously avoided. I have several patients who, if they eat heartily of potatoes, will use so much of their oxygenating capacity that the proteids cannot be perfectly oxidized, and the fourth result in Table I. (line 4) is quickly made evident, by the urine being loaded with uric acid and urates within twenty-four hours after the ingestion of the potatoes.

Assuming also that there is a deficiency in the quality of the bile, either with an increased or decreased quantity, usually the latter, this condition needs early medicinal attention. First, it is wise to sweep the old bile from the system, which can be accomplished in a number of ways, such as by administration of from ten to twenty grains of calomel, alone or combined with a little jalap, or by administering fifteen or twenty grains of blue mass combined with a compound cathartic pill.

In some of the more obstinate cases the following triturate is very effective:

℞.—Bichloride of mercury Arsenious acid	} of each	1 grain.
Powdered ipecac	. . .	2 grains.
Calomel	. . . . .	15 grains.—M.

Divide into fifteen tablets of which one may be given every four hours until six or ten have been taken.

The bichloride, arsenic, and ipecac all stimulate the hepatic cells and cause them to pour forth a larger quantity of bile, and the small and often-repeated doses of calomel excite at the end of twenty-four or forty-eight hours a brisk cholagogue action. By this combined action a very large quantity of the poor and useless bile is forced out of the system and room made for a new and active supply, and bodily oxidation is greatly improved. After ridding the system of the old bile, new bile must be supplied, which is best accomplished by the use of the following formula:

℞.—Inspissated ox-gall	. . .	40 grains.
Sulphate of quinine	. . .	1 drachm.
Compound extract of colocynth	. . . .	10 to 20 grains.
Extract of taraxacum	. .	½ drachm.

Divide into twenty capsules, of which one should be taken three times daily before meals.

By giving the milk warm together with this inspissated-bile pill, the casein will be precipitated in fine feathery flakes and placed in a form to be most easily acted upon by the gastric and intestinal ferments. The bile reaching the intestinal canal helps to prevent decomposition, accelerates peristalsis, improves intestinal digestion, and hastens absorption. From the intestine some of this newly-acquired bile passes up together with the more perfectly liquefied food-stuffs to the liver, and furnishes to the hepatic cells fresh and new bile from which to manufacture a natural supply of biliary fluid. It also seems to aid the hepatic cells in their food-transforming power, as indicated by a decrease or disappearance from the urine of albumin, glucose, oxalates, uric acid and urates, with a marked rise in the percentage of urea.

Sufficient colocynth or some other cathartic agent should be added to the above-mentioned pill to insure one or two smooth well-formed passages daily; even slight looseness of the bowels is often of advantage and does not weaken the patient. The form of cathartic to be added will often have to be changed to meet the varying conditions of the system. Good judgment in the selection of the remedies to be used is absolutely essential, if the greatest success is to be attained in the management of these cases.

Associated with these conditions there is always imperfect innervation, especially of the nerves distributed to the digestive and hepatic organs, and in fact through-

[1] Prepared by Dr. Dadirrian, 213 Second Avenue, New York.

out the whole splenic arcade. This may be overcome by the following combination:

℞.—Sulphate of strychnine . . 1 grain.
Hydrochlorate of caffeine } of each 1 drachm.
Extract of damiana }
Hydrochlorate of cocaine . . 20 grains.
Extract of taraxacum . . ½ drachm.

Divide into twenty pills, of which one should be taken three times daily.

The strychnine serves as a bitter tonic and acts like an electric stimulant to the spinal centres and nerves distributed throughout the splenic arcade, thus primarily stimulating the glands which they supply to increased activity. The strychnine and caffeine stimulate the heart's action and raise the arterial tension, both of which are abnormally low, so much so as to be decided elements in preventing a perfect nutritive condition. The caffeine and damiana, especially the latter, are powerful nutritive tonics to the cerebro-spinal centres and motor nerves distributed throughout the splenic arcade. The cocaine is not added unless the pain from pressure upon the solar plexus is considerable or has been long continued and caused a persistent hyperæsthetic condition of the abdominal nerves. Hyoscyamus at times may be of service for its particular stimulating action upon the vasomotor nerves.

By scrupulously adhering to this plan of dieting, and by a judicious adjustment of the medicinal agents so as to assist nature in her defective condition, a very large percentage of these so-called chronic dyspeptics can be completely and permanently cured. The same can be said regarding Bright's disease, rheumatism, the uric-acid diathesis, diabetes, etc.

But treatment must not be stopped as soon as the patient commences to feel better; it must be continued for weeks and in some cases for months, until nature has had time to displace all the damaged protoplasmic elements and replace them with new and sound structures. When this rule is followed, the cure will be permanent, otherwise an early recurrence of the symptoms may be expected.

HOSPITAL NOTES.

WOMAN'S HOSPITAL OF PHILADELPHIA.

Service of JOHN B. ROBERTS, M.D.,
PROFESSOR OF SURGERY.

[Reported by Mary E. Allen, M.D., Demonstrator of Surgery.]

RADICAL OPERATION FOR UMBILICAL HERNIA.

A woman, forty-six years old, entered the hospital May 19, 1890, for operation upon an enormous umbilical hernia of four years' duration. Her health had been good until the appearance of the hernia, which was produced by lifting a heavy stove. Even the sudden protrusion of a part of the intestines through the abdominal rupture did not cause her to take to her bed, although she suffered from pain in the back, sides, and lower part of abdomen.

The mass increased in size, and after a time became dropsical, until the tumor reached to her knees. On May 12th, just before her admission to the hospital, the thinned walls of the hernia ruptured, and a bucketful of dropsical fluid escaped. On May 18th she had a second discharge of a smaller quantity of the same kind of fluid. The next day she entered the hospital, complaining of borborygmus, accompanied by severe pain, although she had regular movements from the bowels. She also had nausea and a very poor appetite. The urine contained oxalates and red blood-cells. Upon the tumor were found several ulcerated openings, through which the discharge had taken place.

A few days later she had some chilliness, followed by a rise of temperature, and on May 25th her temperature was 101.6°. Later she had severe pain in the tumor, and occasionally vomited a greenish material. When the sinuses leading into the hernia were dressed, there was a discharge of about three teaspoonfuls of pus.

On June 13th she was etherized for the purpose of having a radical operation performed. The tumor at this time was about one foot in length, and rather more in width. The abdominal walls were thoroughly cleansed and an incision made, just large enough to permit exploration of the sac, in the hope that reduction might be accomplished. The omentum and bowel were, however, everywhere adherent, and it was impossible to reduce the bowel without making a larger opening. The incision was made by thrusting a grooved director through one of the former openings and cutting upward upon it. Following the incision there was a free discharge of fœtid serum. A great deal of inflammatory lymph was found upon the intestine, omentum, and walls of the sac. Masses of this lymph were stripped off and removed; and, as it seemed impossible to return the congested omentum to the abdominal cavity, much of it was ligated in masses and removed. At the lower portion of the sac the lymph was in layers, increasing the thickness of the walls to half an inch. The intestines were also very much congested and friable, so that in breaking up the adhesions between them the two outer coats of the bowel were ruptured at one point for about an inch. This was at once carefully sutured with catgut. Finally, the lower margin of the hernial ring was entirely freed from adhesions, but above they were too firm to be broken up. The process of reduction was now accomplished through the lower part of the opening, which was enlarged a fourth of an inch by a hernia knife, leaving the stumps of the omentum and a portion of the colon still adherent to the upper border of the ring. The stumps of the adherent omentum made an excellent plug with which to clear the opening, and were accordingly stitched in position, after the abdominal cavity had been thoroughly irrigated with boiled water and dried with sponges. No drainage-tube was used, and no ligatures to bleeding vessels, torsion being sufficient. A large portion of the wall of the sac and skin were now cut away, including the thickened mass at the lower part of the tumor, and the walls were then securely sutured over the hernial opening. Antiseptic dressings were applied, and the patient was placed in bed in excellent condition. Her temperature was 101.2° F., and pulse 104. A mustard plaster was placed over her stomach, and she did not vomit till three o'clock on the following morning.

On June 14th, at noon, her temperature was 101.4° F., and pulse 136. Her abdomen was becoming tympanitic,

and four doses of Rochelle salt, of half an ounce each, were given at intervals of half an hour. Five grains of quinine in suppositories were also given every two hours. The administration of the Rochelle salt was followed by an enema of turpentine, egg, and water. Her bowels then moved, the stool being thin and containing shreds. In the evening assafœtida was added to the quinine suppositories. Small quantities of liquid food were given from time to time, and usually retained.

At midnight her temperature was 103.2° F., and pulse 146. She was very weak, and 20 drops of tincture of digitalis were given by the rectum.

Dr. Roberts saw the patient again at 3 A M. June 15th, when she was immediately placed upon the operating-table, the dressings removed, and the wound thoroughly cleansed with bichloride solution. The stitches were removed from the lower angle of the wound in both the skin and peritoneal opening, and a glass drainage-tube introduced into the abdominal cavity, which was then thoroughly washed out with boiled water at a temperature of 110° F. The return water contained numerous flakes of lymph slightly tinged with blood. The tube was allowed to remain for drainage, and the dressings were reapplied. The patient, however, died at 7.30 A.M.

Autopsy five hours after death. The external wound had healed by first intention, as had also the peritoneal opening, except where the drainage-tube had been introduced. The intestines had also united. There was a small quantity of lymph and serum in the abdominal cavity. The part of the intestines not included in the sac was in good condition; the remaining portion was much congested, and showed some recent adhesions between the liver and diaphragm, and between the liver and the intestines. The transverse colon, which was not seen at the time of the operation, was very much congested, being, in places, almost gangrenous. Both the large and small intestine were greatly distended. No hæmorrhage had taken place. The omental stumps were in good condition. The patient's death was evidently due to septic peritonitis.

MEDICAL PROGRESS.

The Treatment of Whooping-cough. — The following treatment, is used very largely by certain of the leading specialists in diseases of children in Paris, for the treatment of whooping-cough. The treatment is divided into three periods. The patient should remain in one room or in bed, and the physician employs belladonna and small doses of opium with aconite, as in the following prescription:

℞.—Tincture of aconite
Tincture of belladonna
Camphorated tincture of opium } of each 1 drachm.

Two to five drops once or twice a day, according to the age of the child, is the proper dose. If there is no febrile movement the amount of the aconite can be much decreased, and if constipation is present the opium should not be used. In the second period, or when vomiting comes on, ipecac may be given in small amounts to allay gastric irritation, and in the third period when convalescence is established cod-liver oil, tonics, and Fowler's solution will be found of service.

The Treatment of Eczema of the Nostrils.—COPOZI recommends the use of the following lotion in the treatment of eczema of the nostrils:

℞.—Powdered chloride of sodium
Powdered bicarbonate of sodium
Powdered borax
Powdered salicylic acid } of each 75 grains.

Mix, and dissolve a large pinch of this powder in a wineglassful of hot water and employ the solution as a wash for the eczematous patch. At night it is well to dress the part with oxide of zinc ointment in the strength of ten per cent.

Inhalations for Ozæna.—MOIRE recommends the following to be used as a fumigation in the treatment of fœtid nasal catarrh:

℞.—Camphor	1½	drachms.
Tincture of iodine	3	"
Iodide of potassium	30	grains.
Tar	3½	drachms.
Ninety-per-cent. alcohol	3	ounces.
Water	6	"

Place this solution on a water-bath and inhale the fumes for two or three minutes, after which the nasal chambers should be washed out with a spray of 1-to-100 of carbolized water.

Ointment for Hæmorrhoids.—AUDHOUI recommends, in *L'Union Médicale*, the following ointment for hæmorrhoids:

℞.—Extract of belladonna, " thebaia	of each, 15	grains.
Antipyrine	45	"
Mercury ointment	2½	drachms.
Simple cerate	1	ounce.

This is to be made into an ointment and applied to the inflamed hæmorrhoids. Rectal injections of warm water are to be employed, if constipation is present.

Toxic Symptoms produced by the Instillation of Cocaine Solution into the Cavity of the Middle Ear.—DR. FICANO, director of the dispensary for diseases of the ear in the Hospital Saint-Saverio de Palerme (*Gazetta degli Ospitali*), writes that accidents due to the absorption of cocaine by the different passages into which the drug has been introduced are not rare. Those which follow simple applications to the skin in non-toxic doses seem to be due to certain idiosyncrasies difficult to explain. Accidents of this nature following instillation into the cavity of the middle ear, are but little known, and Ficano regards the following case as worthy of special mention. A woman, aged forty-five years, had suffered for a long time from tinnitus aurium, which had become intolerable. There was a moderate dry otitis, with a diminution in the acuteness of the hearing. Treatment by insufflation of air after the method of Politzer, with instillations of a few drops of five per cent. cocaine solution into the cavity by means of a catheter, was shortly followed by vertigo, nausea, vomiting, cramps, an ineffec-

tual desire to go to stool, etc. The symptoms lasted for several hours, and closely resembled sea-sickness. When we consider the small dose employed, it is doubtful if this was a case of true poisoning, and yet all the symptoms of poisoning were present. An ischæmic action upon the mucous membrane of the ear must be admitted, together with diminution of the circulation in the labyrinth, producing a modification in the tension of the internal ear; or there was a retraction of the mucous membrane of the ear cavity, producing a compression of the labyrinth, and acting upon the oval window; or, finally, the cocaine in modifying the quantity of liquid in the internal ear, modified also the endo-labyrinthine tension. Whatever the mechanism, there was produced a want of equilibrium in the fluid of the internal ear, with grave consecutive troubles. Practitioners should take pains to become acquainted with these dangers, in order to guard against the immoderate use of cocaine. The utility of the drug is undoubted in many of these cases, but it should be employed with great prudence, and in very small doses.

Treatment of Pneumonia in Children.—In the *Revue Générale de Clinique et de Thérapeutique*, the following method pursued by ST. PHILIP is given for the treatment of pneumonia in children. For the relief of the congestion he advises that quinine shall be administered by the mouth, by the rectum, or hypodermically. If failure of respiration exists it may be well to give the sulphate of quinine in a cup of black coffee. If the circulation is in a condition of excitement and there is much fever, from one to two drops of tincture of aconite every three hours should be given, and if the bronchitis is intense syrup of ipecac should be employed. If the quinine is given hypodermically it should be prescribed as follows:

℞.—Hydrochlorate of quinine . . 30 grains.
Glycerin } of each . 2½ drachms.
Distilled water }

Twenty minims of this solution may be injected hypodermically, and it is better to warm it before doing so.

If suffocative catarrh comes on, recourse should be had to counter-irritation in the form of mustard-plasters or large blisters over the chest, or in other cases wet cups may be employed. The latter, however, are not to be used if the child is very young. If much nervous excitement is present opium should not be given, but tepid baths should be administered and antipyrine cautiously used. When the cough is troublesome inhalations of steam may be advisable. If the case becomes very serious and seems about to pass into a condition of collapse the aconite should be stopped at once and quinine and caffeine given by the mouth or hypodermically.

These drugs may be well supplemented by the use of digitalis and alcohol. Oxygen inhalations may be employed if the dyspnœa is marked, and injections of ether may be useful if sudden cardiac failure seems imminent.

Treatment of Cold Abscess.—The employment of ethereal solutions of iodoform in the treatment of cold abscesses, often causes a great deal of pain. In consequence of this BILLROTH employs the following treatment:

The abscess is thoroughly opened across its greatest diameter, and its walls are rubbed with a tampon of iodoform-gauze. After this the cavity is washed out with a solution of corrosive sublimate of the strength of 1 to 3000, and finally after the edges of the wound have been sutured a mixture composed of 100 parts of glycerin and 10 parts of iodoform is injected through a drainage-tube, and allowed to remain in contact with the diseased surfaces.

The Treatment of Chlorosis by Copper.—MM. Pecholier and Saint-Pierre concluded from experiments upon animals with the subacetate of copper, and from observations upon persons engaged in manufacturing this salt, that verdigris, if absorbed slowly and constantly, favors the production of fat, and that women employed in the manufacture of verdigris are not subject to chlorosis. LIÉGEOIS, influenced by these conclusions, has administered copper to thirty chlorotic patients with excellent results. For this purpose he employed the pills of the aceto-phosphate of copper recommended by Luton in the treatment of tuberculosis. The formula of this pill is as follows:

℞.—Neutral acetate of copper . . ⅙ grain.
Crystallized phosphate of sodium ¾ "
Liquorice powder } of each a sufficient quantity.
Glycerin }
M.—For one pill.

If the patients were suffering from amenorrhœa, menorrhagia, or leucorrhœa, Liégeois added from ¾ to 1½ grains of freshly-powdered ergot to each pill. One or two pills were given at the beginning of the midday and evening meals, preceded by from 15 to 30 drops of the tincture of nux vomica or 3 drops of the "bitters of Baumé." During or at the end of the meal a tablespoonful of the syrup of peppermint, containing diluted hydrochloric acid, was taken. This treatment was continued without interruption for from one to three months, and never produced nausea, gastralgia, or vomiting. A suitable hygiene and an appropriate diet were, of course, instituted. Under this treatment the condition of the patients improved, as shown by the color of the face and mucous membranes; the former emaciation was replaced by plumpness, and the visceral symptoms, including dyspepsia, disappeared.

As to the manner in which the copper cures chlorosis, Liégeois is of the opinion that, like the hypophosphites, the chloride of sodium, manganese, and arsenic, it stimulates the gaseous interchange between the blood and the tissues—hæmatosis—and also the functions of the digestive apparatus. The latter is shown by the increasing appetite and by a more rapid and perfect assimilation of iron.—*Revue Générale de Clinique et de Thérapeutique*, January 7, 1891.

A Mixture for Simple Colic.—DUJARDIN-BEAUMETZ it is stated recommends the following mixture in the treatment of colic.

℞.—Strong chloroform-water . 4 ounces.
Decoction of orange-flowers . 4 "
Tincture of capsicum . . 2 drachms.

A dessertspoonful of this mixture may be given every fifteen minutes until the pain is relieved.

Current Literature.

SATURDAY, FEBRUARY 28, 1891.

TREATMENT OF SIMPLE CHANCRE.

Du Castel writes that the treatment of simple chancres is essentially different from that of syphilitic chancres. While in the latter there is back of the lesion a specific poison, which will produce a general infectious disease, even though excision be practised in the first few hours after its appearance, in the simple chancre the conditions are absolutely different; no general infection follows its appearance, but local, inflammatory, suppurative, and gangrenous complications may easily arise. Instead of remaining solitary, as does the syphilitic chancre, it may multiply indefinitely. The danger of simple chancre lies, therefore, for the most part, in its virulence and in the ease with which it re-inoculates the tissues. The object of treatment, then, must be to destroy its virulence and to convert the ulcer into a simple wound. Ablation of the sore Du Castel regards as bad treatment, as there is danger of the fresh surface being inoculated in the process of removal The best mode of treatment is the use of either the actual cautery or powerful chemical caustics. In applying these, care must be taken to reach all parts of the sore, for if any part escapes destruction it will furnish a virus capable of infecting the wound made by the caustic. The use of the thermo- and galvano-cautery, and of electrolysis, as recommended by Apostoli, is attended with intense suffering, and Du Castel prefers chemical caustics.

Ricord employed the carbo-sulphuric caustic, which is composed of sulphuric acid and powdered vegetable charcoal combined in the proportions necessary to make a paste, which is applied to the chancres. This paste quickly dries and forms a sort of scab, which remains adherent to the sore for several days. When it falls off there remains a simple wound, free from virulence, which soon heals. This application, however, is attended with very severe pain.

M. Diday prefers Canquoin's paste—chloride of zinc. This is applied to the chancre, which should be well cleansed, but should not be bleeding, care being taken to cover the whole surface. Around the edge of the paste is applied a small circle of diachylon ointment, while a few drops of collodion are allowed to fall upon the surface of the paste. At the end of from one to three hours the diachylon ointment is removed and the collodion dissolved with ether. The paste is then readily detached, when the face of the eschar is found perfectly dry. If a suppurating spot remains, the cauterization has been incomplete, and the paste must be at once re-applied. The eschar formed by this method falls off on the sixth day, leaving a healthy wound which soon heals. This method is comparatively painless.

The destruction of a chancre by caustics is always a serious operation, and has a number of contra-indications. The loss of substance which it entails and the cicatrix which results render it absolutely impracticable in the treatment of a certain number of simple chancres, such as those of the meatus or of the urethra. In cases of multiple chancres, if all cannot be treated at the same time, it is better not to cauterize any of them, because of the danger of re-infection. When the chancre shows a tendency to cicatrize, caustics should not be used. Wherever, from the form or seat of the chancre, such as subpreputial chancres with phimosis, the application will be imperfect, it should not be made.

When the patient is unable to bear such active treatment, it is necessary to employ some milder method. The ferro-potassic tartrate, according to Ricord, has a specific action upon phagedænic chancres. Such ulcers should be dressed with pieces of charpie soaked in the following solution:

℞.—Ferro-potassic tartrate . . 7½ drachms.
Distilled water . . . 6½ ounces.

M. Diday recommends the employment of a solution of silver nitrate, 12½ grains to 5 drachms of distilled water. Pledgets of cotton soaked in this solution are applied to the sore three times daily.—*La Tribune Médicale*, December 25, 1890.

CAMPHORIC ACID AND THE TELLURATE OF SODIUM AS ANTISUDORIFICS.

I. In the *Bulletin Générale de Thérapeutique* of January 13, 1891, Combemale has published his clinical researches upon these two drugs. Camphoric acid, the formula of which is $C_8H_{14}(CO.OH)_2$, is made by heating camphor with ten times its weight of azotic acid. It occurs in flakes or colorless needles, which are transparent and bitter to the taste; it melts at 70°, and is slightly soluble in cold water, a little more so in boiling water, and readily so alcohol, ether, the fatty oils, and essences. Bertagnini (*Annales de chimie et pharmacie*, tom. xcvii. p. 248), experimenting with it upon himself, took by the mouth five drachms in two days without noticing any effect; he noted, however, that it could be recovered, undecomposed, from the urine. Lew (*Centralblatt für klinische Medizin*, 1890) has noted that when administered to tubercular patients subject to profuse sweats, in the large amount of half a drachm, or even one drachm in two doses, the one in the afternoon and the other in the evening, it produced an antisudorific effect, manifested some hours after absorption. The suppression, in some cases, did not occur until the next day, but occasionally the effect of a single dose persisted for several days. If, instead of giving the camphoric acid internally, an alcoholic solution was used locally, the same results were obtained. The substance never gives rise to untoward symptoms, either near or remote. Dreesmann (*Allgemeine medicinische Central-zeitung*, May 24, 1890) concludes that the drug does not act through the central nervous system, but by destroying the soluble products of the tubercle bacilli, which are the direct cause of the profuse sweats during the stage of pulmonary ulceration.

Combemale, in a series of seven observations, administered camphoric acid in doses of half a drachm daily, the whole amount being taken in a single dose at seven o'clock in the evening. From these studies he deduced the following conclusions:

1. Camphoric acid has a certain action upon the nocturnal sweats of tuberculosis; it very often causes them to cease, and is rarely without some effect.

2. These antisudorific effects are produced from the use of half a drachm per diem.

3. No disagreeable or dangerous effects, worthy of note, accompany the employment of the drug.

4. Camphoric acid acts in tuberculosis the more surely if the pulmonary lesions are not purulent.

II. Tellurate of sodium, $Na_2TeO_4 + 5H_2O$, as its name indicates, is a sodium salt of tellurium. It is obtained by heating a mixture of tellurium, or of its biniodide, with sodium, or with the azotate of sodium, or by the action of chlorine upon a tellurite in alkaline solution. It is soluble in water and alcohol, and occurs, after evaporation, in the form of a gummy mass, or as an amorphous whitish powder. The other tellurates of sodium, the acid tellurate, the white, and the yellow, are less soluble in water.

In experimenting with this drug Combemale has administered it in doses varying from one-third to three-quarters of a grain per diem, the time of administration being seven o'clock in the evening. The patients, all of whom presented the symptom of excessive sweating, were suffering from various disorders, tuberculosis, typhoid fever, acute articular rheumatism, and ulcer of the stomach. He arrived at the following conclusions from the results obtained:

1. The tellurate of sodium possesses a powerful influence over the night-sweats of phthisis.

2. These antisudorific effects are produced with certainty by doses of three-quarters of a grain per diem. Doses of from one-third to one-half grain do not give as sure or as pronounced effects.

3. After prolonged ingestion of the tellurate, some secondary troubles are apt to be produced; a garlicky odor of the breath shows itself occasionally.

4. The tellurate succeeds in all phases of pulmonary tuberculosis; but to stop the secretion of perspiration the dose should be in direct proportion to the advanced stage of the phthisis.

In comparing the relative value of the two drugs just studied, the tellurate of sodium is found to be superior in its antisudorific powers, and the most certain in its action. Combemale also decides that it is the best drug as yet introduced into the pharmacopœia for the profuse sweats of phthisis, and after this he prefers the camphoric acid. Not only do these drugs act favorably in phthisis, but in the sweatings of numerous diseases, such as rheumatism, typhoid fever, syphilitic pulmonary cavities, and dyspepsia. Their action is antiseptic in its nature, since they destroy the soluble microbic products, and thus stop the abnormal process.

THE EMPLOYMENT OF SALOL, BETOL, AND ARISTOL.

It has been well shown by Dreyfous and Hirtz that salol is a good antiseptic for the urinary passages and the intestinal tract. Recently it has been largely used by a Swiss physician, Weber, in the treatment of infantile diarrhœa, and under its influence the symptoms rapidly disappeared, the vomiting being arrested and the diarrhœa ceasing. He gave it in doses of three grains, with two drops of wine of opium twice daily.

The intestinal disturbances, which frequently antedate malarial diseases, call for two therapeutic measures, namely, quinine and an intestinal antiseptic. To meet the second indication salol has been found useful, because it divides in the intestinal canal into salicylic and carbolic acids, both of which check fermentation. The salol is rapidly eliminated with the urine. The dose in which it should be employed in such cases varies according to the age of the patient. To a newborn child, from one to three grains; to a child of two years, from three to seven grains; and to older children, from fifteen to thirty grains, may be given daily. This drug is also of service in the diarrhœas of typhoid fever and tuberculosis.

Betol (naphtalol or salinaphtol) is a salicylate of naphtol, made by the action of beta-naphtol upon salicylic acid, and appears as a white, crystalline, odorless powder. It is insoluble in water, slightly soluble in alcohol and in oils, and has rather an agreeable taste, which facilitates its administration to children, and it is especially valuable because its toxic property is very feeble. It is also useful in the treatment of adults, and may be administered by either the rectum or the stomach. For rectal use it may be employed as an injection, the formula of which, as proposed by Marcigney, is as follows:

℞.—Betol	½ drachm.
Borate of sodium . .	80 grains.
Weak infusion of eucalyptus .	1½ pints.

It may be put up in cachets, each containing seven and a half grains. It may be associated with salol, or salicylate of bismuth, or both, or with the bicarbonate of sodium, prepared chalk, or magnesia. The following preparation is of special service in infancy:

℞.—Betol, from . . .	15 to 30 grains.
Syrup of orange-flower .	7½ drachms.
Mucilage water . .	5 "

Of this a dessertspoonful should be given in twenty-four hours.

The betol may also be administered in milk. It is an excellent intestinal antiseptic.

Aristol (the biniodide of dithymol) is rapidly coming into favor as an excellent substitute for iodoform. It possesses all the therapeutic properties of iodoform without having the inconveniences of its odor and its irritant and poisonous action. It is a reddish-brown amorphous powder, becoming more and more pale as it loses its iodine from exposure to heat or light. It is soluble in water, and glycerin, slightly so in alcohol, and very soluble in ether, chloroform, and liquid vaseline. The powdered aristol has already rendered great service as a cicatrizing agent in ulceration of the skin and mucous membranes, in epitheliomata, in ulcers of the leg,

and in tuberculous aud syphilitic ulcerations. Its application to these ulcerations is not painful, nor does it produce any of the phenomena of general poisoning, as does iodoform. Under the form of a pomade containing from ten to twenty parts of aristol to one hundred of vaseline, it has been used in cutaneous diseases, such as psoriases, eczema, lupus, etc. Some observers have employed it in diseases of the nose, throat, and larynx, and it has been used in gynecological practice in the treatment of endometritis, erosions of the cervix, and vulvar eczema. Swieciki has made pencils and suppositories thus:

℞.—Aristol . . . . . 80 grains.
Gum arabic, a sufficient quantity to make five pencils.

And

℞.—Aristol . . . . 7½ to 15 grains.
Ol. theobrom., sufficient to make one vaginal suppository.

It may be used in ethereal solution, or in collodion if so desired.

Internally it has been given in pill-form associated with the hyposulphite of sodium in cases of fœtid bronchitis and gangrene of the lung, with excellent results. In four or five days the sputa lose their offensive odor and the general condition is greatly improved. In pulmonary phthisis it diminishes the amount of expectoration.—Huchard, in *Revue Générale de Clinique et de Thérapeutique*, January 14, 1891.

THE TREATMENT OF SYPHILIS.

Professor Köbner, of Berlin, at the conclusion of a discussion on "The Treatment of Syphilis," gave the following *résumé* of his experience and opinions.

1. Regarding excision of the primary affection, in only a small minority of cases was he able to prevent further symptoms of syphilis by this means. As a method of operation he recommends excision combined with electro-cauterization. It is indicated as a prophylactic only at an early stage of the chancre, and in extensive breaking down of the induration, or, if the latter is obstinate to ordinary treatment, for the purpose of removing the focus of the disease. The extirpation of inflamed inguinal glands is still more rarely successful and absolutely futile if deeper glands are involved.

2. He does not believe in the preventive treatment of syphilis by mercury, and thinks that the use of the remedy should be limited to hastening the healing of a serious primary sore, and to diminishing the danger of contagion, as in the case of a man with a family.

3. He considers the continuous mercurial treatment of Fournier by no means infallible, and for many cases superfluous, as demonstrated by several cases.

This method should be limited to certain indications, as to impending marriage or grave localization of the disease.

He further calls attention to the destructive influence of mercury on the digestion and on the nervous system.

In harmony with the majority of the specialists who attended the International Medical Congress, he refutes Fournier's statement that syphilis becomes "*presque fatalement tertiaire*" without a saturation of the system for years with mercury.

Mercury alone cannot cure syphilis in a person who was not previously healthy, unless the health is greatly improved by hygienic treatment. Upon the hygienic management he lays great stress.

In several individuals, who could not take mercury by the mouth, the rectal administration proved efficient and safe.—*Berliner klinische Wochenschrift*, December 29, 1890.

TREATMENT OF CONSTRICTIONS OF THE ILEO-CÆCAL VALVE.

Péan divides constrictions of the ileo-cæcal valve into two classes, those due to neoplasms and those of inflammatory origin. Various methods of treatment have been suggested: Maydl, Barton, and Jessop have formed an artificial anus above the joint of constriction; Barton resorted to digital divulsion, and Kraussold, Maydl, and Barton have not hesitated to perform resection. Péan suggests, as a new form of treatment, dilatation at the point where the constriction exists without taking away any portion of the intestinal tube. This is done as follows: An inch and a half above and parallel to the fold of the groin, an incision is made through the skin and cellular tissue from the anterior superior iliac spine to the spine of the pubes, and for half this distance through the aponeurosis and muscles. An opening through the peritoneum, half an inch long, is then made. Bleeding vessels are clamped and all antiseptic precautions observed. As soon as the ileo-cæcal valve is discovered the bowel is tied above and below the cæcum with a rubber tube, which is passed through the mesentery by the aid of sharp-pointed forceps. These precautions having been taken, the intestinal wall is incised at the level of and at each side of the valve for a distance of three inches. After washing the internal surface with a solution of carbolic acid (1-to-100), the condition of the valve can be ascertained. All abnormal tissue filling up the lumen of the bowel is then cut away close to the mucous membrane. This being done, the two extremities of the intestinal wound are brought together by means of the forceps. The incision, which was at first longitudinal, takes now the form of a lozenge, two sides of which are represented by the lips of the small intestine and the other two by those of the large intestine. Bringing the forceps nearer together the incision becomes transverse, and in this position the edges are sutured. Catgut is used to unite the mucous membrane and muscular coat, and silk for the outer portion of the muscular and the serous coat. The ends of the latter are cut off close. The rubber tubes are then untied, and soon after this the blood resumes its course in the vessels, and the fæcal matter begins to pass through the bowel with incredible rapidity. Should the sutures give way and gas and

fæces escape, the abdominal cavity should be washed out with sublimate solution, and the stitches re-inserted. Iodoform is dusted over the bowel, the abdominal wound is closed and covered with a dressing of iodoformized, sublimated wadding.

The reasons of Péan for preferring this mode of operation are:

1. That it is easily performed, since the surgeon operates upon a superficial portion of the bowel, and one which is easily seen.

2. It requires a smaller number of sutures than does resection, which shortens the duration of the operation, and diminishes the chances of perforation, of fæcal fistula, of an artificial anus and of septic peritonitis.

3. It does not give rise to a circular constriction, as does resection.

4. Finally, it establishes at the place of constriction, a dilatation large enough for the fæcal matters to pass through.—*Bulletin de l'Académie de Médecine*, December 30, 1890.

REVIEWS.

PHYSICIANS' LEISURE LIBRARY, No. 6; MODERN TREATMENT OF HEADACHES. By ALLAN MCLANE HAMILTON, M.D. Detroit: George S. Davis, 1890.

THE chief value of this book to the ordinary practitioner of medicine will be the prescriptions which are to be found on almost every page, and also in the directions which are given for the application of electricity and other external methods of giving relief to persons suffering from headache. The book, like most of its series, does not profess to be a very deep or learned account of this most frequent symptom of disease, and is, in consequence, not loaded down with much bibliography, but with practical material.

The author recognizes the fact that gout and rheumatism are often the cause of a great deal of cephalic pain, and is not content with describing the treatment of headache by drugs but also gives instructions as to the diet.

A BIOGRAPHY OF EPHRAIM MCDOWELL; WITH ARTICLES RELATING TO OVARIOTOMY. By MARY Y. RIDENBAUGH. New York: Charles L. Webster & Co., 1890.

THE author of this work is the granddaughter of the man who has been called the "father of ovariotomy," and she has been sufficiently impartial to include both those things which are favorable and unfavorable to this great surgeon. After reading the details of his life we are told of his idiosyncrasies and those of his relatives, more particularly concerning James Nash McDowell, a nephew, who was so bitter toward Abraham Lincoln that the following authentic story is told of him:

"The Doctor had a crank idea that in that commodious building one room should be set apart and designated as 'Hell,' in commemoration of Abraham Lincoln, who, although long since dead, held a bitter place in the heart of the eccentric old doctor. It was my pleasure to visit my relative (Dr. McDowell) soon after he refitted up his college and residence; and after his congratulations of meeting were over he remarked that he wanted to take me to 'Hell.' Not comprehending his meaning, I replied, 'I hope I shall never be so unfortunate as to see H—l.'

"He immediately caught me by the arm, and leading me through several narrow hallways, we finally halted in front of a very heavy double door, when drawing a large brass key from his pocket and placing it in the lock, the door soon yielded and swung wide open.

"I noticed as I passed into this strange room that the word 'Hell' in gilt letters stood out in bold relief over the entrance. The room was very long and narrow, and lacked carpet or other furniture.

"On entering this Dantean abode, the first salutation that greeted me was the venomous hissing of an unusually large rattlesnake, that was to be seen darting out its fiery tongue between the bars of its cage.

"To the left a huge crocodile was noticed, such as crowd the southern sloughs and bayous, and dot the lowlands and canebrakes of the tropical country. The hideous reptile crept slothfully through his pool of tepid water, now and then swinging his immense jaws as though he would like to make a meal of us; but he too was confined within his own limits, and there was no danger.

"Becoming interested in this weird and unnatural place I followed the Doctor, not unwillingly and certainly with a much aroused curiosity, deeper into the mysteries of his 'Hell.'

"Glancing to our right we saw the bird of ill omen perched upon his pole, seemingly oblivious of us or of its surrounding; occasionally it would grit its bill together, causing a peculiar unwelcome sound. Alongside the bird was a lizard, singing its unvaried song.

"At the extreme end of the narrow hall-like room a gallows had been erected, suspended from which was an effigy of ex-President Abraham Lincoln. For a moment (the scene was so life-like) I was shocked and startled.

"There were several other images, one in particular representing Lucifer and his imps. It was a novel sight to witness. Dr. McDowell took a lively interest in everything connected with this particular apartment."

The book loses part of its value from the absence of an index, although the table of contents is sufficiently voluminous to give a very good idea of what it contains. The labor of collecting the material for its pages must have been very great, and we hope that the author will sell a sufficient number of copies to remunerate her for her expenditure of time and money.

CORRESPONDENCE.

CHICAGO.

ACCORDING to the last report of the Chicago Board of Health, the registered deaths from all causes in this city for the past year were 16,946. Of these, 724 were by accidents, 182 by suicides, 45 by murderous shootings, stabbings, blows, and violence; 215 women from confinement, miscarriage, or abortion; 295 children were born defective or died of causes incident to birth, and 3 persons were found dead, making 1482 deaths not caused by sickness. Deducting the above from the total mor-

tality, we have 15,464 deaths from sickness. Of these, 5499, or 35 per cent. of the whole, were from diseases of the respiratory tract. Consumption caused 1556 deaths; pneumonia, 1170; bronchitis, 876, and so on throughout the list. 1705 deaths were from diseases of the pharynx and larynx, and 3794 from disease of the tubes and tissues of the lungs.

The foundation for a complete cottage system has been laid here for insane patients. The four cottages now almost completed are model institutions, everything connected with them being of the latest improved pattern. They were erected at a cost of $55,933. The small percentage of patients cured at the insane asylum compared with the State institutions is undoubtedly due partly to the fact that the State institutions send their incurable cases from this county to Dunning and partly to the arrangement of the buildings. Many cures cannot be effected unless the patients are properly classified, and this cannot be done in any other way than by the cottage system.

Dr. John A. Benson, Superintendent of the Insane Asylum at Jefferson, presented his annual report to the Public Service Committee a few days since. During the year 470 patients were admitted, and the daily average of inmates was 1066.

The late Professor James Adams Allen donated his large and valuable library to the Presbyterian Hospital for the special service of the staff. It may be used, however, by the permission of the superintendent, for reference by members of the profession and by the students of Rush Medical College.

The new edifice of the Woman's Medical College contains everything to be desired in the way of offices, laboratories, dressing- and study-rooms, and a commodious amphitheatre unrivalled for comfort and convenience. One of the amphitheatres of the old building is still retained for chemical and anatomical lectures, so that the new rooms are kept free from the disagreeable odors necessarily connected with these departments.

Dr. I. N. Danforth reported to the Pathological Society a case of tubercular disease of the kidneys and bladder, and presented the diseased organs.

The patient was a man, thirty years of age. About four years prior to his death he began to experience pain in the region of the left kidney, and shortly after that the urine became purulent but remained normal in amount and free from blood. The symptoms, in the main, were negative. The amount of pus was not enough to indicate a cyst of the kidney or any great amount of trouble with the bladder. He had no elevation of temperature; and there was no cardiac disease, but an anæmic condition developed. His appetite and digestion failed; and he gradually lost flesh.

The autopsy revealed a tubercular deposit in the upper lobe of the left lung, with two or three small recent cavities, but no other disease except the lesion of the left kidney, ureter, and bladder, which were presented for examination. The ureter was pervious, although the passage was small, but did not communicate with the bladder. The kidney was enormously large and lobuated. The bladder was somewhat thickened, and at the point where the left ureter should enter the bladder there was a hard, fibrous mass, which could very easily occlude the ureter.

Dr. Henry T. Byford, in speaking of the healing of open wounds without suppuration, in a clinical lecture, said that the secret of causing a wound to heal without suppuration is really known to but few, although the principle is known to all. The principle involved in the method he uses is that germs cannot develop without moisture, and the whole secret consists in keeping the wound dry.

His method is to pack the cavity loosely with sterilized gauze if it be large or with sterilized absorbent cotton if small, and use a dry aseptic dressing over all. Neither iodoform nor any other powder should come between the packing and the dry gauze over it, for powder interferes with efficient capillary drainage and the sterilizing process. In extraperitoneal wounds, the packing should be changed from two to four times daily, if the discharge is serous or purulent, until the packing is no longer wet through, then once a day, then once in two days until the dried surfaces have contracted. As long as the discharge is purulent or abundant, he washes the cutaneous edges with alcohol at each dressing to keep the skin clean. The cavity is merely dried out thoroughly with absorbent cotton or gauze, and neither drugs nor moisture allowed in it. In hospital wards, where serous cavities are frequently opened, this method he considers invaluable, since it enables us to do away, to a great extent, with suppuration and its dangers.

"DIGESTION, ASSIMILATION, AND OXIDATION."

To the Editor of The Medical News,

Sir: I wish to call attention to several statements which were made in the lecture on "Digestion, Assimilation, and Oxidation: their Normal and Abnormal Conditions in Relation to Health and Disease," in The Medical News, January 10, 1891. These statements, if not absolutely incorrect, are certainly misleading and not in accordance with the facts and experiments of progressive physiological chemistry. The points to which exception is taken are contained in the following sentences, which, for the sake of clearness, are quoted intact: "The chemico-physiological activity of the saliva is located in the ptyalin, which is an organic *nitrogenous* ferment, having for its function the hydration of starch, or the conversion of starch into maltose, conveying it, as it were, one step forward in the chemico-physiological process. This action is effected in *only an alkaline* solution, or in an *acid medium* the percentage-acidity of which has not exceeded *ten per cent.*"

First, in regard to the nature of the ferment which produces this change in the amylaceous elements of food, the writer states unrestrictedly that it is an organic nitrogenous body. Although elaborate methods are employed by which there may be obtained from saliva solutions which appear to be almost entirely free from proteids and yet are intensely amylolytic, "even these"—so says Foster—"probably contain other bodies besides the really active constituent." "Whatever," he continues, "the active substance be in itself, it exists in such extremely small quantities that it has never yet been satisfactorily isolated; and, indeed, the only clear evidence of its existence is the manifestation of its peculiar powers." It seems hazardous, therefore, to make any dogmatic statement concerning substances which, like

ptyalin, pepsin, amylopsin, or the enzymes in general, have been obtained in such small quantities at a time and in a state of such questionable purity that their exact chemical characters have not yet been ascertained.

The most elaborate method and the one most employed in obtaining the digestive ferments in a state of comparative purity is that by which Brücke separated what he termed pepsin. This method depends upon the ferments being carried down from solutions with precipitates produced in them. Cohnheim applied this method of Brücke to the saliva, and employed calcium phosphate as a precipitate to carry down ptyalin. But calcium phosphate carries down with it not only the ptyalin, but also the albumin and doubtless other proteid matters in the saliva. The complete separation of these bodies from ptyalin is very difficult and the final analysis of the substance obtained, showing the presence of nitrogen, has led to the assumption on insufficient grounds that ptyalin is nitrogenous. The only real proof, aside from this imperfect analysis, rests on the fact that its action is destroyed by boiling.

Next, in regard to the medium in which the saliva exhibits this peculiar amylolytic power, and the hindering or destructive influence of acids and alkalies on the diastatic action of the salivary ferment. Dr. Porter states that "this action is effected only in an alkaline solution or in an acid medium the percentage-acidity of which has not exceeded ten per cent."

The early experiments employed to demonstrate this point and from which the above conclusions, or similar ones, have been drawn, were inadequate, because based on rough calculations and a neglect of the real reaction of the chemical substances used. The starch used was apt to be acid in its reaction, and the normal alkalinity of the saliva (0.080 per cent., calculated as sodium carbonate) was not properly taken into account.

It is undoubtedly true, as a general principle, that the conditions in the body-economy are the best suited to the ends they are intended to accomplish. This argument has been used as one method of demonstrating that the natural and true acid secretion of the gastric juice is hydrochloric rather than lactic acid. The fact that pepsin is found experimentally to digest proteid matter most readily and completely in hydrochloric acid solution is an argument in favor of that acid as the one really provided and employed by nature. Thus, since the saliva is normally alkaline in its reaction, it is fair to suppose that the action of its ferment would be most manifest in such a medium. The experiments by which it was proved that such was not the case, although interesting, historically, in showing how a popular and well-grounded belief must yield to precise scientific investigation can only be alluded to here and the steps of proof given in passing.

At some time previous to 1885 it was demonstrated by Chittenden and Ely that neutralized saliva had as great diastatic power as the unneutralized or normally alkaline saliva. Even in this experiment the recorded result plainly indicated a greater diastatic power on the part of the neutralized saliva, the alkaline saliva converting 41.58 per cent. of the starch into sugar, while the same quantity of neutralized saliva changed 43.28 per cent. Although in this experiment the amount of saliva used was large, and thus an element of possible error introduced, still every precaution of precision was taken, and the starch employed was manufactured by the experimenters in such a way that it should be absolutely neutral in its reaction.

In 1884 Langley and Eves[1] made the statement, unaccompanied by data, that "neutralized saliva converts starch into sugar much more actively than unneutralized saliva." These two statements are quoted by Chittenden and Smith[2] in their article on "The Diastatic Action of Saliva," as the only two recorded statements up to that time regarding the relative diastatic action of the neutralized and normally alkaline secretion. The experiments of Chittenden and Smith show that there is a very great difference in the action of ptyalin in neutralized and unneutralized saliva—a difference more manifest when the saliva is greatly diluted, the explanation of which will appear later.

The influence of sodium carbonate on the diastatic action of saliva has also been made the subject of experiment, and the conclusion of Chittenden and Smith is that "even much less than 0.0015 per cent. of sodium carbonate with unneutralized diluted saliva may decidedly retard the action of the ferment, while in similarly diluted saliva 0.005 per cent. of sodium carbonate may prevent diastatic action almost entirely."

As to the influence of acids on the diastatic action of saliva, Dr. Porter states that the action is effected "in an acid medium, the percentage-acidity of which has not exceeded *ten per cent.*" A large number of experiments to demonstrate the influence of acids on the diastatic action of saliva have been made by Langley and Eves, Chittenden and Ely, and Chittenden and Smith, and attention has been called to the fact that no definite statement can be made as to the absolute percentage of acid necessary to hinder or destroy the ferment's action. For there are two very important elements which come in to modify the influence of the acid or alkali, and which permit of only a general statement or a statement for a saliva of a certain dilution. These are the conditions of the acid or alkali, whether free or combined, and the amount of proteid matter present.

That the presence of proteids influences the diastatic action has been proven, and it has been pointed out by Chittenden and Smith[3] that in addition to the combination of peptone and acid, the proteid matter manifests a direct stimulating influence. Thus the presence of 0.025 per cent. hydrochloric acid prevented the conversion of but 3.50 per cent. of the starch into sugar, the presence of 1 per cent. of peptone allowed the conversion of 48.85 per cent. of the starch.

The method recommended by Danilewsky for the detection of free acid by the use of tropæolin OO dissolved in methyl alcohol, now enables us to distinguish free acid present from that combined. Both combined and free acids influence the action of saliva, and both have a hindering and destructive action. The combined acid (or presence of acid-proteids, formed by the action of the acid on the proteid matter in the saliva) causes an increased action of the ptyalin, except when present in comparatively large amount, so that while combined

[1] Journal of Physiology, vol. iv. No. 1.
[2] Transactions of the Connecticut Academy, vol. vi.
[3] Loc. cit.

acid has some destructive action, the retarding influence of the larger percentage of acid-peptones is out of all proportion to their power of destruction.

In testing the influence of *free* acids on the diastatic action, it must be borne in mind that the normal alkalinity of the saliva is 0.080 calculated as sodium carbonate, and that the saliva contains a certain amount of proteid matter. When the saliva has been very carefully neutralized and its proteids just saturated, it is found that 0.0010 per cent. of *free* acid appreciably diminishes the saliva's action, and 0.0030 per cent. almost entirely stops the amylolytic action. Moreover, acid approximating to the strength of the acid of the gastric juice has a *destructive* action on the salivary ferment, The action of 0.002 or even 0.005 per cent. of hydrochloric acid for thirty minutes, causes little if any destruction of the ferment, since on neutralization diastatic action is vigorously continued. Pronounced destruction does take place with 0.005 to 0 010 per cent. of free hydrochloric acid. Thus, we see that under no condition could the amylolytic action of the ferment take place in an acid medium the acidity of which was 10 per cent.

The importance of this subject is shown from its bearing on the amylolytic action of saliva in the stomach. It is well known that during the early stages of digestion, there is no *free* acid in the stomach, and that as digestion in the stomach proceeds the acidity increases. Thus the amylolytic ferment of the saliva undoubtedly continues its action on the starchy foods for some time in the stomach and until its acid-proteids increase in amount and approach to their point of saturation. Even before *free* acid makes its appearance, the diastatic action may entirely stop, and all salivary ferment must ultimately be destroyed in the stomach.

The writer in his classification of food-stuffs says, "so far as nourishing or building up any of the component parts of the body is concerned, starch, sugar, and fat furnish *no nutriment* to the system and in this sense I shall continue to speak of the CHO compounds as being absolutely non-nutritious, and only of service to the body in so far as they yield heat, energy, lubrication, and *rotundity of form*." And again he divides the food-stuffs into two classes, first, "the *nutritious* albuminous, nitrogenous, or CHNOS compounds, and, second, the *non-nutritious* starches, sugars, and fats, or the CHO compounds."

In making this division of food-stuffs into *heat-producers* and *tissue-formers*, he has adopted a classification which Huxley calls "misleading and indeed erroneous." That the proteids are oxidized is undoubted and their oxidation, as well as the oxidation of non-nitrogenous foods, must give rise to heat and energy. And from the evidence of carbonaceous waste when a muscle contracts there is reason to think that the non-nitrogenous foods may also be directly built up into the tissues. Mr. Huxley says, moreover, that "as soon as the elements of the food, in fact, get into the blood, the distinction between the two classes is lost; *both* form tissues, and *both* supply heat." For this reason Huxley prefers the classification of the vital food-stuffs into the *essential*, or proteids, they alone being, in the nature of things, necessary to life; and the *accessory*, or fats, sugars, and starches, which, however important, are not absolutely necessary.

Finally, Dr. Porter states regarding the digestive action of the gastric juice that "the *nitrogenous* envelope surrounding the starch-granule or oil-globule may be digested away, thus setting free the granulose and oil." This he calls the starch-hydrating and fat-freeing action of the stomach.

According to the teaching of organic chemistry we learn that starch is a white, velvety hygroscopic powder consisting of round or elongated granules in concentric layers, the interior of these granules being granulose and their husk cellulose. A possible erythro-granulose may exist. These chemical substances are, however, in all text-books of organic chemistry, classed among the carbohydrates and are never credited with any nitrogen. Their formula $(C_6H_{10}O_5)_n$ shows that besides carbon they contain only hydrogen and oxygen, always, too, in the same proportion in which their elements are present in water, therefore, they (and this of course includes the starch-envelope) are true carbohydrates and non-nitrogenous.

NEWS ITEMS.

Report on Koch's Lymph to the Dauphin County Medical Society.—At a recent meeting of the Dauphin County Medical Society, Drs. E. H. Coover, Thomas J. DuNott, and Hugh Hamilton reported upon Koch's lymph after many observations in the hospitals of New York and Philadelphia, which they had visited. This committee regard the discovery as one of much importance, its power being intense, the rapidity of its cure unparalleled; but the committee warns the profession and the public against the dangers of the method in the hands of unskilful persons. In treatment by the lymph the most salubrious surroundings are necessary, the diagnosis must be absolutely correct and the control of the patient by the physicians unquestioned. Such conditions are alone attainable in proper hospitals or in private with the best environments.

American Electro-therapeutic Association.—The American Electro-therapeutic Association was organized on January 22, 1891, at the Academy of Medicine, No. 17 West Forty-third Street, New York, by the adoption of a Constitution and By-laws, and the election of the following officers:

President.—G. Betton Massey, M.D., of Philadelphia.

Vice-Presidents.—William James Morton, M.D., and Augustin H. Goelet, M.D., of New York.

Secretary.—William H. Walling, M.D., of Philadelphia.

Treasurer.—George H. Rohé, M.D., of Baltimore.

Executive Council.—Horatio R. Bigelow, M.D., of Philadelphia; Franklin H. Martin, M.D., of Chicago; William F. Hutchinson, M.D., of Providence, R. I.; Frederic Peterson, M.D., of New York; and Chauncey D. Palmer, M.D., of Cincinnati, Ohio.

The object of the Association, as stated in Article II. of the Constitution, is "The cultivation and promotion of knowledge in whatever relates to the application of electricity in medicine and surgery."

The Association starts with a strong and vigorous

membership, and has every prospect of a most useful and successful career.

The next meeting will be held in Philadelphia, in September of this year.

William H. Walling, M.D., Secretary, 2005 Arch Street, Philadelphia, Pa.

Marine-Hospital Service.—The annual report of Dr. John B. Hamilton has been made to the Secretary of the Treasury for the year ending June 30, 1890. The medical inspection of immigrants in New York harbor is a newly-assumed duty that, during the latter part of the fiscal year, fell to the charge of this service. It is expected that a hospital and asylum will presently be required, to be established on Ellis Island, in order to deal humanely and efficiently with some of the unfortunates who are shipped to this country as an economical way of disposing of troublesome charges. In regard to the constant menace from Cuban yellow fever, the report avers that this country would be a gainer, in a pecuniary sense, if it could give to the Cuban Government sufficient funds to make and keep Havana a healthful seaport. The past year was the ninety-first of the existence of the service.

Suit for Damages on Account of Pain after Amputation.—This suit was brought for damages against a railway corporation, the result of an accident which was the occasion of the amputation. The case was heard in the courts of New York State, and was carried up to the Court of Appeals; the defendant was the Delaware, Lackawanna and Western Railway. The action was brought to obtain compensation for damages, because of a "special kind of pain" complained of after the amputation of an arm, namely, a pain which is located in the member that has been cut off. The plaintiff was allowed to testify on the trial that he had suffered continuous pains seemingly located in the amputated hand and arm, and on appeal it was argued that such testimony should not be allowed. The appellate court has recently decided that this objection was not well taken, and that the plaintiff's evidence was competent. One of the points raised by the defence was that this pain in the hand and arm of the plaintiff was purely imaginary and a delusion, and that, because the arm had been cut off, there could not possibly be any pain located therein. The Court of Appeals meets this contention by means of the following answer from the standpoint of law: "The reason urged in support of the exception is that such pain was imaginary and a pure delusion and was not a direct or a natural result of the injury received; the plaintiff had testified that this was a part of the painful suffering he had endured after the accident and the amputation of the arm, and whatever was its nature, if his testimony was true, the sensation was that of pain and the result of the injury. Pain is but the sensation of a condition that produces it, and the fact that it seemed to come from or to reside in the hand, as if its connection with the body remained, is only descriptive of the pain he suffered. It was no less the subject of consideration because the location of it was deceptive."

Plain Statement from the Medical and Surgical College of New Jersey.—The Medical and Surgical College of the State of New Jersey has just published a "Plain Statement" of its contest with the health authorities of Jersey City. It is published in a pamphlet of forty-six pages, and is probably as candid a statement as was ever made by any so-called college; it contains enough testimony against itself to damage the faculty forever. The head of the concern is proved, by this pamphlet issued over his own signature, to be an offspring of the bogus institution run by "Dr." Buchanan under the style of the Eclectic Medical College of Pennsylvania, and to be an advertising specialist residing in New York City. Connected with the scheme are several men who have doubtful reputations. According to the statement of the Hudson County Medical Society (THE MEDICAL NEWS, February 7, 1891), the so-called college has never had any of the conveniences or requisites which would enable its so-called students to attend either hospital instruction, clinics, or anatomical demonstrations. One of the students stated, however, that there had been two dissections of sheep's heads, and one of a calf's heart. It does not appear from the pages of this pamphlet that any reputable citizen of New Jersey has ever been, or has ever been invited to be, connected with the undertaking. Nevertheless, there have been allowed to "graduate" two classes, one containing twelve persons, and the last containing three; one of these persons only claimed a residence within the limits of New Jersey.

Medical Organization in Japan.—The *Tei-I-Kwai Medical Journal* of Tokyo, Japan, November 22d, describes in idiomatic language the establishment of a national society of the medical men who have studied their profession in America and Europe. It says: "The principal leaders in Tokyo caused themselves to start a medical association for the object of which they have to gather all the medical brethren in every province of the Empire and to exchange their knowledges. The endeavor of them brought this scheme to born in April first under the name of the First Japanese Medical Association, the meeting was held for a week and was closed with every success. It was hoped to hold this Association in future once every four years." There are not more than 5000 who have the knowledges above referred to, but they stand in the forefront of reform, "for indeed the reformation of Japanese medicine is the task of them, for this object they join to constitute medical societies and respective society endeavors to publish their journal."

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

DIPHTHERIA: ITS CAUSE AND TREATMENT.[1]

BY WILLIAM P. MUNN, M.D.,
OF DENVER, COL.

THE almost constant prevalence and the unmitigated fatality of diphtheria make it a subject for the consideration of which no apology is necessary. It is as constant and important a factor in our mortality reports as is consumption or typhoid fever, and yet, notwithstanding the frequent opportunities to study it, there still exists some uncertainty as to its mode of origin. Does it originate in the local lesion, or is the local lesion a result of the systemic affection? In considering this question we must remember that the lesion may and often does exist elsewhere than in the fauces, sometimes making its appearance there as one of the later manifestations, and occasionally altogether failing to appear. The original local lesion may exist in an unobserved portion of the nares or larynx, and being for some days uninterfered with, the systemic disease may manifest itself prior to the discovery of any lesion in the throat. Such a case would *appear* to prove the secondary character of the faucial exudate, but it can by no means be held to prove the systemic origin of the disease, especially since we know not only that a local lesion *may* exist for days without the occurrence of any constitutional symptoms, but that it is occasionally, though rarely, the only manifestation of the disease. The weight of evidence seems to be in favor of a local origin, and the apparent preference for the nose and fauces is most reasonably explained by the hypothesis that the germ is usually inhaled or swallowed, and is, of course, more liable to find lodgement there than at any other point. Then, too, abrasions of the mucous membrane in this locality are of frequent occurrence and offer a favorable spot for germ-lodgement and growth, while the rich lymphatic supply of the throat provides an open avenue for systemic infection. In connection with this we know that children who are catarrhal seem to be especially susceptible to the disease, and that in them it is apt to be of a severe type. The predilection which diphtheria seems to have for certain families may be explained by the fact that those families are catarrhal, *i. e.*, every member of the family may have susceptible mucous membranes, not of the nose and throat alone, but also of the digestive and genito-urinary tracts. I have more than once observed the coincidence of this susceptibility with the occurrence and recurrence of a peculiarly malignant type of diphtheria.

The cause of diphtheria is at present very generally supposed to be bacterial, but whether the bacteria themselves, or the ptomaïnes resulting from bacterial life and growth, are the cause is not yet determined. Several investigators claim to have isolated the specific bacillus, or coccus, as the case may be, and each one is morally certain that his is the morbific agent. The Klebs-Löffler bacillus and the streptococcus diphtheriæ of Prudden seem to have a more definite relationship to the disease than have any other microörganisms yet isolated, and it is possible that both forms may have a connective relation to similar necrotic processes, the clinical phenomena resulting therefrom being identical.

This supposition is not entirely hypothetical, but, on the contrary, is entirely in accord with the general trend of late bacteriological investigations. For example, certain forms of pleurisy are plainly of a non-microbic origin, being dependent on rheumatism, plumbism, or similar conditions causing chemical changes in the blood, while the microbic variety may be due to the presence of anyone of a number of microörganisms — among those which have already been found being the tubercle bacillus, the typhoid fever bacillus, the streptococci, the staphylococci, and the encapsulated diplococci of Fränkel.[1] A very interesting suggestive fact in this connection is that the streptococcus diphtheriæ of Prudden[2] seems to be identical with the streptococcus erysipelatous and the streptococcus pyogenes, varieties of micrococci with which bacteriologists have been familiar for some time. This identity is proven, not simply by morphological resemblances, but by a series of biological and chemical tests and control experiments. This discovery points to an explanation of the oft-noted clinical relationship of diphtheria, erysipelas, and scarlatina. However close may be the primary causative relationship of the coccus to the disease, there ensue during the pro-

[1] Read before the Denver Medical Association and Arapahoe County Medical Society, December 18, 1890.

[1] Third Italian Congress of Internal Medicine. THE MEDICAL NEWS, December 13, 1890.

[2] American Journal of the Medical Sciences, April and May, 1889.

gress of the disease certain pathological changes with which the coccus does not seem to be intimately concerned, as well as the immediate changes of which it may undoubtedly be considered the exciting cause.

Locally the pathological changes occur in the following order: ulceration and modification of epithelial cells, migration of leucocytes, and exudation of fibrin and lymph. Constitutionally, the disease manifests itself as a malignant, disintegrating, and degenerating force acting upon the blood, which it probably reaches indirectly through the medium of the lymphatics. There is a manifestly increased tendency to fibrin formation as evidenced by the character of the faucial membranes as well as by the exudates which occur in any portion of the body where a synchronous inflammation or injury exists. There is also an influence exerted which disintegrates the red blood-corpuscles, or failing in that, interferes with the performance of their functions as oxygen-carriers; thus lowering vitality, retarding nutrition, and preventing the proper elimination of waste products. It is asserted that bacteria cannot exist in living, active, circulating blood, and if this be so, then the hæmatic changes just described cannot be due to the *immediate* action of the so-called diphtheria germs, but *may* be due to the chemical affinity of their ptomaïnes for the hæmoglobin of the red blood-corpuscles.

So much for the theoretical pathology of the diphtheritic processes, a problem still enveloped in more or less uncertainty. But it seems that modern investigation is daily approaching more closely to the solution, and we may soon expect to appreciate definitely the true nature of this the most horrible of modern contagious diseases, and to gain from that knowledge some indication as to the proper treatment, perhaps even a revelation as to its absolute prevention.

It is unnecessary in a paper of this character to dwell upon the symptomatology and course of the disease, that being a subject with which every practitioner is only too familiar.

In regard to fatality, it has been my experience that different epidemics seem to vary—one year the major portion of all the cases recover, the next year the majority die, and this occurs irrespective of the treatment adopted. It is a general rule, however, that the severity of the case depends on the extent of the membrane and the rapidity of its formation. Of cases in which the tonsils only are involved, we rarely lose more than 10 per cent. If the nose and palate are involved, about 50 per cent. die; if the larynx only is invaded, 75 per cent. die; while if the nose, fauces, and larynx are all invaded, at least 90 per cent of the cases will be lost.

The occurrence of temporary paresis as a sequel of diphtheria is a very common event, possibly the soft palate is most often affected, although in my own experience strabismus has occurred about as frequently as paralysis of the palate. The vocal cords and the peronei muscles of the leg come next in frequency of involvement, while multiple paralyses and general paresis are infrequent. The patients generally recover from local palsies, with little or no medication, although general tonics and electrical stimulation are never out of place.

I have twice seen beginning anterior spinal curvature as a sequel of diphtheria: in one case in a girl of twenty years at the second lumbar vertebra; in the other at the cervical region in a girl of six years. Sayre's plaster-jacket and the "jury mast"—with the preparations of iron, the phosphates, and cod-liver oil internally—arrested its progress in both cases. I have never had permanent paralysis in any of my own patients, although, no doubt, it sometimes cannot be avoided. The number of such cases would be very much diminished if all cases of diphtheria were kept under surveillance and treatment for some time after recovery.

Suppuration of lymphatic glands, especially of those of the neck, is a sequel of somewhat frequent occurrence, and should be treated upon the same general principles which apply to such suppuration occurring under other circumstances.

Differential diagnosis. — There are only a few conditions liable to be confounded with diphtheria by competent observers. When a membranous exudate accompanies the angina of scarlatina the conditions resemble those of diphtheria so closely that an error in diagnosis may well be excused, especially if the scarlatinal rash happens to be suppressed. Indeed, we may well ask whether the pathological conditions present are not exactly similar in both cases, and the query comes with additional force when we remember that Prudden has found the same streptococcus present in scarlatina, diphtheria, erysipelas, septic pneumonia, and simple phlegmonous inflammations. He suggests that its action may be modified and its virulence diminished by the chemical constituents present in the secretions under varying conditions. Whether this can be proven we do not yet know, but there is certainly enough positive knowledge to enable us to assert the close relationship, if not absolute identity, of the pathological processes in the two diseases. Clinical evidences of this relationship occur with great frequency. I may cite the following:

A family moved to a short street which for a year had been absolutely free from diphtheria, and from scarlatina for three years. The house into which they moved was new and had never before been occupied. Their infant child, a year and a half old, was suffering from scarlatina, which fact they

suppressed and as soon as the child had recovered they moved away without disinfecting the sickroom. As soon as the house was vacated, the children of the neighborhood went into this room to play, and in less than a week four of them were prostrated with a severe type of scarlatina. Every one of the four had been in the room. On the fauces of one of them an exudate appeared, and the rash in her case did not make its appearance until about the tenth day of her illness. When this child recovered she was allowed to keep a doll with which she had played while ill, and the doll in a few days passed into the possession of the children of a neighbor all of whom had suffered from scarlatina three years before. Three of these children were then seized with diphtheria, the membrane invading the nose in all, and in one extending into the larynx, with fatal results.

Being fully conversant with every circumstance of these cases, all but two having been under my personal care, I am certain that no other source of contagion existed, and that the last patients contracted diphtheria from the antecedent cases of scarlatina.

A less dangerous affection, which is often pronounced to be diphtheria; but which, as a rule is promptly recovered from, is ulcerative follicular tonsillitis. The infectious character of this disease and the slight resemblance of its muco-purulent exudate to the fibrinous exudate of diphtheria, may readily cause a mistake if the examination is superficial, but if the examiner takes the trouble to mop off the secretion with a little absorbent cotton fastened on a probe, the resemblance disappears. An actual mistake in discriminating between this condition and that which characterizes diphtheria, is of rare occurrence; but a great many practitioners, especially those of the homœopathic persuasion, prefer to call such cases diphtheria.

It will be noted that I have not thus far used the word "croup," and for this omission there are several reasons, viz.:

Croup is not properly the name of a disease, only a *symptom* which may occur in connection with any form of laryngitis, or as a simple reflex act. I can conceive of no tangible reason for dignifying a symptom by calling it a disease simply because it occurs when the diphtheritic process originates in the larynx or happens to invade it secondarily.

W. W. Johnston[1] insists that he has many times made post-mortem examinations of children who have died of what he calls "true croup," and that he invariably found the larynx filled with a fibrinous membrane, but that *no* ulceration was present. This last fact he regards as pathognomonic; if ulceration is present it is diphtheria, if ulceration is absent it is "true croup," which, he alleges is never contagious. If this be so, then the inoculation of healthy animals with material from the "true croup" membrane will be innocuous; but if the advocates of "true croup" have in late years attempted to substantiate by experiments their assertion of the non-contagious character of the disease it is not generally known.

On the other hand, those cases which are claimed to be typical examples of "true croup" almost invariably accompany or are associated in some way with diphtheria, and such invariable association can only be explained by the supposition that the two diseases are identical.

Fatal cases of croup usually occur in families or localities where diphtheria is prevalent. Non-fatal cases of croup are usually of that variety which finds the patient perfectly well one day, very sick the next day, and perfectly recovered on the third, thus giving rise to the suspicion that the medical attendant had applied the name of true or membranous croup to a case of catarrhal laryngitis, laryngismus stridulus, or hysteria of the larynx.

To my mind, the "membranous croup" of the books is a process, the pathology, clinical appearance, and treatment of which are absolutely identical with those of laryngeal diphtheria, the name croup is a misnomer, and its study as a separate disease has been a mistake, due to the idea that the epithelial surface remains intact in croup, although as Billroth states,[1] the remainder of the pathological processes may be "exactly similar."

Rindfleisch,[2] however, states emphatically that "croupous inflammation is preceded by a loss of epithelial covering," . . . . "the most frequent agent being unquestionably the action of cleft fungi," that being the class name under which he includes all bacteria.

The non-contagious character of croup is not so generally admitted as it once was.

Perfect fairness demands the statement that some of the best pathologists still insist upon the non-identity of croup and diphtheria; and Prudden, while an advocate of their identity, calls attention to the fact that in the investigation of twenty-four cases of diphtheria he failed to find the streptococcus in two cases, one of which had been pronounced by the attending physician to be "croup and not diphtheria." The patient, however, died, and within a few days another child in the same family became fatally ill with all the constitutional and local evidences of *diphtheria*, and "*the streptococci were found*, not only in the membrane, but in the viscera."

Another disease which may occasionally be mistaken for diphtheria, is that variety of putrid sore-

[1] American Journal of Obstetrics, September, 1888.

[1] Surgical Pathology, p. 312.

[2] Elements of Pathology, p. 34.

throat, which also affects the palate, causing œdema of the uvula and in extreme cases sloughing of the parts. Practically this is a phlegmonous inflammation, and if neglected or if the history is not known it may closely resemble diphtheria, but a few days' observation and treatment will, as a rule, clear up the matter, especially since such cases usually occur in adults.

I have seen one peculiar case in a man twenty-four years of age, in which a patch of membrane closely resembling the membrane of diphtheria, covered the tonsil of one side for about two weeks and seemed to defy treatment, although it did not extend. The patient was tubercular and I concluded that it was a tubercular ulceration. Some months later an unexpected discovery in regard to his degraded personal habits, led me to believe that it was of syphilitic origin, and in all probability an initial lesion.

Treatment.—The methods of treatment recommended for diphtheria are many. From time to time there arises an apostle of some new, or the resurrector of some old plan of treatment, who will laud his method to the skies, claiming for it invariable success and for *himself* the infallibility of an all-wise physician. Such men and measures rarely, I might say, never hold their own during two successive epidemics.

While it seems improbable that we will ever discover a remedy which will cure diphtheria as quinine cures malaria, yet it is by no means improbable that in the near future a method of inoculation will be discovered that will materially lessen the frequency of its occurrence or perhaps entirely eradicate the disease.

In the present state of our knowledge, however, it seems wise that we should map out a line of treatment by classifying certain morbid conditions which usually accompany or result from diphtheria, and that we should then, upon general therapeutic principles, combat these conditions or destroy their causes by the use of the most potent remedies in our materia medica. This may lead to multiplication of remedies, but it allows the widest latitude for the exercise of the discretion of individual practitioners, as well as for the adaptation of remedial measures to the idiosyncrasies of individual patients. It is a rational plan, and at least as successful as any other now in vogue. Treatment must be general and local. In considering the indications for general treatment we find that there are four, as follows:

1. Diphtheria is essentially a debilitating disease; it wears out the heart and it shatters the nervous system. If the patient does not die from any other cause he will die from heart-failure or nerve-fag; hence it is important that from the first he should receive positive and persistent stimulation and nutrition to the utmost limit of his capacity. The stimulant should be a diffusible one, prompt, efficient, and reliable. There is one remedy only that will answer all these requirements, and that is *alcohol.* It may be given freely from the beginning of the disease, and with greater frequency and in increased quantity as the circulation demands it. It is useless and foolish to administer it in small quantities. If we wish to have its beneficial action it must be administered freely and steadily. Brandy, whiskey, champagne, or sherry may be used, as the exigencies of the case may require. I have given as much as twelve ounces of whiskey daily to a child four years of age, and had good results. If at any time a more potent and diffusible stimulant, which is at the same time as safe as alcohol should be discovered, I believe it will take its place in the therapy of diphtheria. Digitalin, strychnine, strophanthus, caffeine, camphor, and musk, may be indicated in many cases as adjuvant stimulants, but none of them can supplant alcohol, though they render very efficient service in combating special conditions.

2. Diphtheria is a septic disease, and to antagonize and defeat the septic process the most powerful antiseptic agents must be used. That here, as elsewhere, there may be a variance of opinion as to the most available antiseptic for this particular purpose is by no means surprising. Peroxide of hydrogen, carbolic acid, sulphurous acid, sulphur, eucalyptol, thymol, and the soluble mercuric salts have all their ardent advocates, and all are, no doubt, useful. My personal experience has been favorable to the use of corrosive sublimate on account of its energetic antiseptic action, the smallness of its dose, and its complementary action, of which I will speak further on. A child of six years may be given at first $\frac{1}{80}$ of a grain every two or three hours, and this may soon be increased to $\frac{1}{15}$ or $\frac{1}{10}$ of a grain without ill effects. This dosage may be continued for many days, or even weeks. I have usually given calomel at the same time, and although the total dosage has been in some cases enormous, I have never seen any indications of mercurialism, and what is more to the point, the cases have been favorably modified as to malignancy, duration, and termination.

3. A third indication, which is purely hypothetical, is the supposed tendency of the blood to the formation of fibrin, and for the purpose of counteracting this tendency I am in the habit of giving large and continuous doses of calomel, its action in this matter being assisted by the coincident administration of the corrosive sublimate. The favorable results which so often follow this dosage seem to render the hypothesis more tenable, and while I do

not attempt to explain the process, I recognize the results, and accept them as a sufficient reason for the practice. Under this medication extension of membrane ceases, and the exudate becomes less tough, and hence more easily removed and expectorated, the whole aspect of the patient improving at the same time.

It is to be noted that in diphtheria calomel not only does not salivate, but it has little effect as a cathartic. Why this tolerance should exist we cannot tell, but that it does exist is indisputable.

Some observers have even made it a diagnostic rule, stating it thus:[1] *if moderate doses of calomel produce characteristic stools, the disease is not diphtheria.* My own experience has been somewhat in accord with this, but I do not affirm its uniform application. I have given from 2 to 5 grains of calomel every two hours until the bowels moved, and have observed the movements to be natural in form and consistency when even 40 or 50 grains had been taken. To one apparently desperate case, a boy four years old, I gave 160 grains in three days, with the following results: (1) the bowels moved naturally once a day; (2) the tongue cleaned off and appetite returned; (3) the membrane ceased to extend and began to liquefy, the case progressing favorably from this time on to ultimate recovery.

4. A fourth indication to be met is the disintegration of red blood-corpuscles. We as yet know of no more reasonable method of meeting this indication than by the administration of some preparation of iron. The experience of American physicians seems to justify the use of this remedy quite as positively as the pathological conditions demand it. The tincture of the chloride is the form generally given, in doses of from five to twenty minims, every two or three hours.

These four indications cover the customary demands for the internal medication of diphtheria. I usually prescribe the tincture of the chloride of iron and the corrosive sublimate together in some pleasant menstruum, such as glycerin or syrup of orange, followed by a full dose of whiskey; the calomel should be given from the very first until the bowels are moved once or twice, and afterward repeated, as may be necessary, for that object and for the limitation of membrane formation. It is well taken if administered in the form of tablet triturates dissolved in a little milk. The dosage must, of course, be varied as the exigencies of the case demand, but it must always be borne in mind that in no other disease is medication so absolutely necessary or so well borne, and that to be efficient it must of necessity be heroic. It is probable that under this treatment there are at least twice as many recoveries as under an expectant plan of treatment.

[1] J. C. Lange, 1889.

From time to time, in the last decade, and even within the current year, ardent advocates of the calomel treatment have made for it extravagant claims, to which its more conservative friends can by no means give their assent. Calomel does not and cannot cure all cases of diphtheria. There is no known medication which can achieve such results, and the boastful claimants of such success have, perhaps unconsciously, suppressed all mention of their failures and recorded only their successes. Then the advice to administer calomel without regard to the patient's general condition, until the passages resemble frog-spawn stools, which twenty years ago might be pardoned to Dr. Reiter[1] in his enthusiasm over the revival of an almost forgotten therapeutic method, is at this date, to say the least, exceedingly unwise.

Local treatment aims to do two things:

1. To destroy the disease-germ and render its ptomaïnes inert.

2. To cause softening of the membrane and ultimately its complete removal.

The first object is sought by the application of antiseptic powders, washes, sprays, and gargles. A favorite application with the laity is powdered sulphur, and it has been asserted to be the cause of many marvellous cures. Professional experience with it has, however, not been very satisfactory.

Occasionally, when the original lesion is seen at an early stage, and has not yet attained a large size, it has cleaned off, healed promptly, and been followed by no constitutional disturbance after thorough cauterization with nitrate of silver, carbolic acid, or a strong solution (1 to 50) of corrosive sublimate.

In the nose it is said that the progress of the membrane may be arrested by tamponing the nasal cavity with cotton soaked in a 1-to-100 solution of sublimate, the tampon being renewed every hour.

Spraying or syringing the throat with a 1-to-1000 or 1-to-2000 solution of corrosive sublimate, or 1-to-30 solution of carbolic acid has been of much service. One patient of my own, whose nose, fauces, and larynx were simultaneously invaded, recovered after three weeks of hourly syringing with a 1-to-30 solution of carbolic acid.

Either lime-water as a gargle, or the vapor of slaking lime as an inhalation every half hour, is a most useful adjuvant to our local treatment. After every such application and the use of the spray the patient will expectorate shreds of membrane, and respiration will become easier.

To soften the membrane all the digestive ferments have been made use of, and all are highly efficient. To be efficacious a sufficiently strong

[1] Diphtheria; a monograph. By W. C. Reiter. J. B. Lippincott & Co., Philadelphia, 1878.

solution should be brought thoroughly in contact with the membrane. An alkaline menstruum, such as lime-water or soda-water, is most efficient, and it is not wise to use the ferments in the same solution with corrosive sublimate, since it will materially lessen, if not altogether destroy, their activity. It is better to use them alternately, fifteen or thirty minutes apart.

Moist air, or air saturated with steam, is an adjuvant by no means to be despised. The arrangement known as the "croup kettle" is worthy of trial in every case.

If local applications are to be of any service they should be used frequently and thoroughly. The patient should not be allowed to sleep past the time for the inhalation or spray, but as long as the case is dangerous one or the other of these should be used every half hour, or oftener if very urgent. Not until decided improvement is noted should the interval be increased, and then only with considerable caution. They should be kept up at intervals of two hours or less until every vestige of membrane has disappeared.

As there is great danger of sudden cardiac failure at any time during the course of diptheria, the patient should be prevented from doing anything that will cause an extra effort of the already weakened heart. Cases are not infrequent in which sudden exertion has been followed by instant death.

The operative treatment of laryngeal stenosis is a subject important enough to demand a special paper. My own experience has been limited and disastrous, but I firmly believe that early operation in properly selected cases will prove more successful in the future than in the past. Whether the operation should be intubation, laryngotomy, or tracheotomy, will depend, in a very large percentage of cases, upon the personal predilections or experience of the operator, with this exception that intubation will more often gain the consent of the parents because it is not a "cutting" operation.

Tracheotomy is an operation never to be undertaken lightly. Many writers underrate its difficulties, but the majority of operators will concede that it requires better judgment, more experience, and greater skill than any of the more frequently performed capital operations. The proper performance of intubation requires even a higher degree of skill, and should rarely be undertaken except by an operator who has practised it frequently and successfully upon the cadaver.

DISCUSSION.

Dr. Austin G. Case, in opening the discussion, said that although diphtheria may be local in its origin, the physician is seldom called to see a case before the constitutional symptoms have manifested themselves. In treatment the medication which has given him the best results in one series of cases has frequently failed to benefit in another series, and under such circumstances the practitioner is ready to grasp at anything that seems to offer any chance of success. He has used nearly every form of medication that has been recommended, and has never yet found any remedy that proved to be a specific for diphtheria. In the first stages he has found calomel extremely beneficial, but cannot agree with the theory that it does not produce the characteristic stools in cases of diphtheria. It is his rule to push its administration until such stools do appear, and it may then be diminished, discontinued, or replaced by the bichloride of mercury. As a solvent to the membrane, no application has been so uniformly useful and reliable as the peroxide of hydrogen, and having this remedy, he can conceive of no reason for using other local applications which are much less efficient.

In regard to the operative treatment of laryngeal stenosis, he said that his personal experience with tracheotomy has been disastrous. In his own operations and in the many at which he has assisted, he has never seen a case of tracheotomy for diphtheria recover. Intubation has given him much more satisfactory results, since in a total of fifteen operations he has had five recoveries.

Dr. H. B. Whitney said that the cause of diphtheria is now generally conceded to be the bacillus first described by Klebs and afterward by Löffler. It has been found that inoculation of this bacillus in animals will invariably cause diphtheria. Some recent investigations seem to show that the constitutional symptoms are due not to the bacilli themselves, since these cannot exist in the blood, but to some of their products, which are not, however, ptomaïnes, but closely analogous to proteids. The injection of these proteid products almost uniformly produces the constitutional symptoms of diphtheria, without, however, causing any formation of membrane.

Dr. Rogers was very strongly inclined to believe in the existence of croup and diphtheria as entirely separate disease-processes. Membranous croup is certainly not contagious as is diphtheria, and in illustration of this fact he cited the following incident: A case of croup in a large asylum was, upon the advice of the visiting medical staff, allowed to remain in the centre of the ward with the other children, no precautions being taken to prevent contact. There were no new cases either of croup or of diphtheria. He believed that such instances prove the non-contagiousness of croup.

Dr. Pfieffer described a case in which a temperature of 103°, pulse of 160, and respiration of 40, with a coincident endocardial murmur seemed to indicate an idiopathic endocarditis, but twenty-four hours later a diphtheritic membrane made its appearance in the throat. This case he regarded as one in which the disease was primarily constitutional, the membrane in the throat being a secondary manifestation.

He also described a case of croup in which he performed tracheotomy, and which came very near terminating fatally on account of extension of the membrane below the end of the tracheal tube. He believes in the employment of longer tubes than those generally employed, and thinks that their use would save many

lives, by giving the patient the chance afforded by the self-limitation of the membrane after it has proceeded a certain distance in the trachea.

Dr. N. Weist called attention to the efficacy of peroxide of hydrogen as a solvent and antiseptic, claiming that its use renders unnecessary the employment of sprays of corrosive sublimate. He asked for the experience of others in reference to suppuration of lymphatic glands, since his personal experience has been that it is infrequent.

Dr. Bryant said that in several epidemics he had seen suppuration comparatively frequently—in about 10 per cent. of cases. He called attention to the value of chloride of iron as a local application. It is an important point to bear in mind that strong local applications may destroy the healthy mucous surface and give an opportunity for extension of the membrane. Indeed, in at least one epidemic under his observation he believes that the high mortality-rate was perhaps due to the universal application of concentrated solutions to the whole surface of the fauces.

Dr. J. T. Eskridge had seen a number of cases of multiple neuritis following diphtheria, and thinks that many of the cases of heart-failure in this disease are due to degeneration of the cardiac nerves.

Dr. John Elsner called attention to the value of ferric alum as an application to the membrane, especially if the case is seen early. The solution must be carefully applied by means of a pledget of cotton, to the membrane only. Under this treatment, repeated, if necessary, every three hours, the membrane becomes gray or black, shrivels up, and disappears, and the disease is aborted. This treatment he prefers to all others, and has had his experience confirmed by many others, among them Abraham Jacobi, of New York.

Drs. McLauthlin, Bryant, and Eskridge cited cases of children who had attended school during the whole course of an attack of diphtheria, both themselves and their parents being ignorant of the nature of the illness. In one case the fact of diphtheria having existed was elicited only after the occurrence of paralytic symptoms. These gentlemen urged the importance of having schools supervised or inspected in some manner, so that such occurrences should cease.

Dr. McLauthlin dwelt on the importance of reporting all cases of croup to the health authorities.

Dr. Shallenberger emphasized the relationship of croup and diphtheria, and spoke of the necessity of guarding against infection in all cases of croup, as though they were proven to be diphtheria. He reported a case alleged to be croup which died under the care of another physician, but within a week three adults came under his care with every characteristic symptom of diphtheria.

TWO UNUSUAL DISLOCATIONS.

By JOHN T. DAVISON, M D.,
of Sopris, Colorado.

Dislocation of the fifth metatarsal bone from both attachments.—J. C., a laborer, employed about the mouth of a mine in "making up the trip," while running to turn a switch, slipped and fell, one or two wheels of a loaded pit-car, which weighed three tons, passing over the dorsum of his right foot. When seen a few minutes afterward, the foot was greatly flattened. There was a tumor, almost cylindrical in shape, on the outer side, where the skin was tensely drawn over the bone; there was also a penetrating wound on the inner side just below the malleolus, and, probably, from the great weight acting upon so limited a surface, much subcutaneous bruising, if not rupture, of the tissues had taken place. The dislocation was immediately reduced by seizing the toes with one hand, making traction in the line of foot, and, with the other hand, pressing the bone into place, crepitus being appreciable. There was much swelling, accompanied by great pain. After the partial subsidence of swelling and pain, hot foot-baths twice daily, followed by a snug bandage, and, later, by inunction with neat's-foot oil, was the treatment pursued. About six weeks after the accident, while walking upon crutches, the patient slipped and fell, injuring the foot again, and doubtless retarding recovery. He is now, two months after the original injury, able to bear his weight partly upon the foot without artificial support; there still being considerable tenderness. Beyond slight swelling and discoloration, the foot presents a natural appearance. The patient will probably soon make a good recovery.

Compound dislocation of the ankle-joint, with eversion and backward displacement of foot.—Following the classification recommended by Stimson, I consider this title better calculated to convey an idea of the trauma than is the title "compound Pott's fracture"; for, although the fibula was broken at the usual point above the ankle-joint, the tibia presented none of the lesions characteristic of Pott's fracture.

Mrs. S., aged about forty-five years, quite fleshy, yet withal active, and of good vitality, while visiting Mine No. 4 at Sopris, September 20, 1890, was thrown from a wagon. She alighted upon her feet in such a manner that the distal extremity of the left tibia was forced through the flesh a distance of four inches; and also through the side of her shoe. She was seen at a neighbor's house forty-five minutes after the accident. I found her lying on a sofa, and not suffering as intensely as might be expected from such an injury. As she would not submit to etherization until her husband arrived, I contented myself with giving morphine hypodermically, cutting away the remnants of shoe and stocking, and thoroughly irrigating the protruding bone and the limb with bichloride solution (1 to 2000). The foot and lower part of her leg were finally wrapped in a towel moistened with a 1-to-1000 bichloride solution.

Upon the arrival of her husband she was etherized, and a more thorough examination was made than was possible before. The tibia was found intact, save at the extremity, where it had come in contact with the ground, the dense tissue being abraded in two or three places, exposing the cancellous structure beneath. The interarticular fibro-cartilage was attached to the end. There was a slight rent

in the periosteum, and two or three spiculæ of bone were adherent by the shreds of periosteum where the bone was abraded. As stated in the title, the foot was everted, and turned backward to a considerable extent. The small amount of soft tissue about the ankle was strikingly shown in this case, the foot appearing to hang by a shred. The dislocation was easily reduced by making traction on the foot, and carrying the foot first outward, and then, as the wound of exit came opposite the end of the tibia, inward. Previously to this, however, the little fragments of bone were snipped from their periosteal attachments. The wound of exit, as it appeared with the bone in place, was about one and one-half inches in length, and at a right angle to the shaft of the tibia. Three interrupted sutures were inserted, leaving the lower part of the wound open for drainage. The wound was covered with iodoform, and a saturated solution of naphthalin in ether, as recommended by F. S. Dennis, was poured over a considerable extent of the adjacent surface. Iodoform, bichloride gauze, and bichloride cotton were applied in the usual manner, and the limb immobilized with pasteboard splints, which completed the surgical treatment at this time.

This dressing was allowed to remain twelve days, during which time the temperature presented nothing remarkable, once rising to 102°, but subsiding after giving a purgative, and not rising thereafter above 100⅕°. There was very slight swelling about the wound, and none of the leg and foot. When the dressing was removed granulations in abundance were seen. There were a few drops of pus, probably from a stitch-abscess, as the slight amount of tension sufficed to cause local inflammation of the skin. She was removed to her home in Trinidad two weeks after the accident, and further treatment of the case was continued by Dr. D. G. Thompson, who applied the necessary dressings. The wound healed rapidly, so that passive motion was commenced within a month or six weeks after the injury.

Dr. Thompson, whom, I should state, assisted me at the time of the accident, tells me that three months after the dislocation she had good use of her ankle, and could bear her weight upon the foot, but was still too timid to attempt walking without support of some kind. I have reported this case in considerable detail in order to add a little to the not extensive literature upon the treatment of compound dislocations of the larger joints. The case exemplifies the good results obtained from close attention to asepsis and antisepsis.

A CLINICAL STUDY OF ERGOT.

BY JOHN C. HEMMETER, PH.D., M.B., M.D.,
OF BALTIMORE.

IN a period of medical history when new therapeutic agents are rushed upon us in an abundance which seems out of all proportion to any real increase in our knowledge of the scientific application of drugs, or to any real advancement in experimental therapeutics, a critical combination of facts which have been established in the laboratory and in the hospital concerning ergot may aid in throwing new light on the value and possibilities of one of the oldest drugs in the pharmacopœia.

The therapeutic effects of few drugs correspond so closely with their physiological action as do those of ergot. The following summary of the physiological effects of this substance shows this statement to be true:

I. Ergot causes contraction of involuntary muscular fibre throughout the body. Consequently it produces:

(*a*) Increased uterine contractions.

(*b*) Increased intestinal peristalsis.

(*c*) Constriction of the muscular walls of the arterioles.

(*a*) Very probably, constriction of the involuntary muscle-fibres surrounding the bronchioles.

II. As a result of the constriction of the arteries, ergot causes a rise of arterial pressure. A brief, temporary lowering of pressure preceding the rise, when the drug is injected into the jugular vein, is due to its local poisonous action on the heart (muscular fibre or ganglia).

III. It reduces the number of contractions of the heart in a given time.

IV. The respiratory movements are decreased in number in most animals, including man; in the dog they are increased.

V. It lowers temperature.

VI. The irritability of the peripheral motor nerves is increased, independently of the central organs.[1]

VII. The irritability of the peripheral sensory nerves is diminished, hence reflex excitability is diminished.[2]

VIII. With the retardation of the pulse-beat the height of the pulse-curve is not reduced; in all of our kymographion tracings the altitude of the pulse-curve was unaltered, though the number of systolic contractions were reduced. (This is in agreement with Köhler's and Eberty's results, and opposed to those of Bailly, Hardy, Beatly, and Bonjean.)

IX. Secale reduces the pulse-rate.

Upon the power of ergot to constrict the arterioles and to cause arterial and capillary anæmia depends its application in a large number of disease-conditions. It has been successfully used in hæmoptysis, hæmatemesis, epistaxis, hæmorrhage from the gums; renal, hæmorrhoidal, and vesical hæmorrhage; in the bleeding caused by carcinoma; and in hæmorrhage dependent upon a dyscrasia, as purpura hæmorrhagica. In menorrhagia and

[1] Köhler, Virchow's Archives, lx., 1874.
[2] Köhler, loc. cit.

leucorrhœa, which are produced in certain cases by endometrial congestion; in colliquative sweating due to relaxation of cutaneous capillaries; in enlargement of the spleen and in vascular goitre it has been found of value. Langenbeck[1] instituted a successful treatment of aneurism by secale, and was followed by Dr. Paul Vogt,[2] who states that Schneider cured a femoral aneurism, and Dutoit one of the subclavian artery, with this drug.

Ergot has also been advantageously used in congestive headaches and in impaired vision from congestion of the retina incident to dilated or hypertrophied heart. Intestinal catarrh with diarrhœa, due to congestion of the intestinal mucous membrane, is a special indication for the use of ergot. It has proven itself to be very useful in dysentery and in galactorrhœa. The power of ergot to contract the uterus has been utilized to remove uterine fibroids, by strangling their vascular supply and by causing uterine contraction. There is good authority for crediting it with a beneficial influence over cervicitis, pharyngitis, and even gonorrhœa, and over paralysis of the bladder from distention, or in that due to cerebral or spinal lesion.

The theory of its action is based upon the artificial anæmia which it induces in the arterial vessels, so that the histological process of inflammation is impeded.

In small aneurisms of the peripheral main arterial trunks, Langenbeck held that the drug brought about a cure by contraction of the unstriped muscular fibres in the affected portion of the vessel. We have reason to believe from studies on the rabbit's omentum, and on the frog's web, that the characteristic effect of ergot in constricting blood-vessels and producing arterial, capillary, and venous anæmia is exercised most markedly in those regions which are diseased. The arterioles in the neighborhood of a region undergoing changes coincident with the first stage of inflammation, will be found, micrometrically, to undergo greater degrees of constriction than those in normal regions. Arterioles that are pathologically enlarged seem to require less stimulus to contract than normal ones, because the natural tendency of an expanded muscular coat of an artery is to resume the average lumen which it occupies during normal arterial tension. We therefore have a right to conclude that when ergot is given to a patient suffering from an acute localized inflammation—pneumonia, for instance—its main influence is exercised upon the parts pathologically altered, while those parts of the circulation in which normal arterial tonus has been maintained are but slightly affected.

In most nervous diseases ergot is of doubtful efficacy, except in those forms in which symptoms and signs indicate hyperæmia and congestion of the spinal or cranial meninges, or an acute inflammation of the cord-substance.

In the treatment of the psychoses, in which ophthalmoscopic examination justifies us in diagnosing intra-cranial congestion and, perhaps, inflammation, ergot has proved to be a valuable adjunct to other methods of treatment. The same can be said of its use in certain forms of epilepsy. In locomotor ataxia and diabetes mellitus, ergot has, in our experience, failed to relieve.

The property of diminishing the irritability of the peripheral sensory nerves and the consequent reduction of reflex action, has, according to Köhler[1] been utilized in the treatment of diseases in which the reflex excitability is greatly increased, as in chorea, and certain forms of epilepsy and tetanus.

Although these influences of ergot over peripheral sensory nerves have *per se* little therapeutic utility, they become important in connection with the other well-established effects of the drug. In all acute inflammations, with high fever, rapid pulse, hurried respiration, and congestion, if we can employ a drug which will allay these symptoms and at the same time lower reflex excitability, it is most desirable to do so. The power of ergot to reduce temperature, the number of pulse-beats, the number of respirations, and at the same time maintain increased arterial-pressure, makes it a most important agent in the management of certain conditions in pneumonia.

We shall now proceed to record a series of personal observations (excepting those referring to the obstetric employment of ergot) on the indications for the use of secale and its positive or negative results in the following diseases and conditions:

Labor, pneumonia, bronchitis, hæmoptysis, dysentery, mitral regurgitation, aortic insufficiency, dilatation of the heart, goitre, meningitis, epilepsy, locomotor ataxia, hemicrania, and diabetes mellitus.

ERGOT IN LABOR.—It would require the pen of an experienced obstetrician to do justice to the subject of the use of ergot in labor, but it has been thought expedient to give the drift of opinion as expressed in the literature on the subject since 1878. In these records it appears that the experience of the most authentic authors has not changed the rules for administering ergot in labor since they were first systematically collated by Köhler[2] and copied into most standard works on therapy. These indications are:

I. In lingering labors when the child's head is low, the parts relaxed, the pains absent or feeble, and there is danger in delay from hæmorrhage or other alarming symptoms.

[1] Berlin. klin. Wochenschrift, 1860, vol. vi.
[2] Ibid., March, 1872.

[1] Physiol. Therapeutik, p. 207. [2] Physiol. Therapeutik.

II. When the pains are suspended and convulsions set in, venesection being necessary.

III. In inevitable abortion.

IV. When the placenta is retained, owing to uterine inertia.

V. In post-partum hæmorrhage.

Disease of the uterus, deformity of the pelvis or spine, and similar conditions, forbid its use. Even resistance of the soft parts, as may be anticipated in a primipara, contra-indicates the use of the drug. It has been accused of causing rupture of the uterus, but this is doubtful.[1] The manner of action of ergot upon the uterus in labor is claimed by some to be unlike that of the natural forces. The natural contractions are intermittent and rhythmical, while those under ergot are constant, steady, and, as it were, tetanic, tending to destroy the child by interrupting the placental blood-supply and impeding the fœtal circulation, for the life of the fœtus depends upon the aëration of the blood during the intervals between the expulsive contractions. If it were true that the contractions under ergot were tetanic and without remissions, the respiration of the fœtus would be stopped and its life imperilled. We shall, however, present satisfactory experimental and clinical evidence, on very good authority, that the contractions of the uterus produced by ergot are in every particular normal and not tetanic. Before we proceed to this evidence we may consider the objection to the employment of secale on the grounds that the drug circulating in the maternal blood becomes dangerous to the heart of the child,[2] reducing the number of its beats to 110 or less, and rendering the heart's action feeble and irregular.[3] It is Köhler's[4] opinion that in such cases the dose of the drug has been excessively large, its administration undertaken too early and before the parts were prepared for the expulsion of the child. On the other hand, Garraway[5] resuscitated, by giving ergotin, a newborn babe whose heart-sounds were irregular and scarcely discernible, the child being almost asphyxiated.

This suggestion of treating asphyxia in the newly-born was first made by Dépaul.[6] If any organ is stimulated to function by an irritant applied to its centre in the brain or cord, or to the nerve or nerves going from that centre to the organ, the latter responds in its normal manner, provided the stimulation be not excessive. A muscle will respond to electric stimulation of its nerve by normal contraction, but if the stimulation be too powerful a tetanic contraction is the result. These facts apply mainly to muscle physiology; in organs that give no physical evidence of responding to stimulation we are unable to arrive at similar conclusions, but in the case of the uterus, if a physiological dose of ergot is employed, the result will be normal contractive movements. Whenever tetanus results, one can safely presume that the dose has been toxic. The most recent scientific study of the use of ergot and its action in labor was contributed by Schatz to the Third German Gynecological Congress, at Freiburg.[1] The conclusions of Schatz are, in the main, as follows:

I. The contractions of the uterus, when produced by ergot, in their manner and character do not differ from the normal. Ergot produces properly coördinated contractions of the uterus, provided large doses have not been given, and, hence, most probably acts by direct stimulation of the centre for uterine contraction.

II. In case the contractions are already present, ergot increases their number, but does not render them stronger. The intensity of the force of the contractions is influenced only in proportion to their frequency.

III. As a general rule, in normal labor the force is greatest when the frequency of the contractions is from six to ten in thirty minutes. One should, in the employment of ergot, seek to maintain this frequency and not allow it to exceed ten contractions in thirty minutes.

IV. The action of secale begins fifteen minutes after its administration by the mouth, and is greatest in thirty minutes. One can, therefore, judge of the effect of a dose of the drug only after the second half-hour after it has been given, and should under no circumstances administer it oftener than once in an hour, if one wishes to avoid the risk of producing too frequent and consequently too weak contractions by cumulative action, or of causing uterine tetanus.

V. The effects of a dose last for one hour only, and the drug must, therefore, be repeated hourly. As a general rule, the proper dose to give is a very small one if uterine action has already begun. In order to be sure of avoiding too great a frequency of contraction with all its detrimental effects, it is necessary to begin with from 8 to 10 drops of the fluid extract, for instance,[2] and to increase it with great care, repeating its use not sooner than one hour after the preceding dose.

The deductions of Schatz show much careful observation, and his facts are handled with scientific acumen. His experimental results were obtained by means of the tokodynamometer.

Recent testimony regarding the power of ergot

to cause abortion seems to be divided. If the mother and fœtus are healthy and other irritants are excluded, it is presumed that ergot will not *per se* induce abortion. The expansion of the uterus during gestation is a purely physiological process; ergot, therefore, as a rule, fails when used for criminal purposes (Wright and Bonjean). In pregnant animals, however, abortion seems easily induced by ergot.[1] Ramsbotham[2] found, after numerous trials, that ergot, with few exceptions, promptly induces expulsive action in the human female. On the whole, the abortifacient influence of ergot seems uncertain.[3] It is certain, however, that one of the principal phenomena of ergotism in both animals and the human being is frequent abortion, so that this result will have to be classed with the toxic effects of the drug.

Ergot in Pneumonia.—Dr. N. S. Davis contributed to the *Journal of the American Medical Association*[4] a clinical report of two cases of pneumonia in which certain alarming features of the disease were effectually relieved by the use of ergot. After remarking that there is no fixed rule or routine of treatment which is adapted to all cases of pneumonia, simply because the morbid processes which constitute the different stages of pneumonic inflammation are liable to be much modified by the previous condition of the patient and the coincident meteorological and sanitary influences that surround him, he designates the benefits to be derived from ergot. When there is a demand for more steadiness and tone in the action of the heart, he asserts that if given in connection with digitalis it is perhaps the most reliable agent that we possess for resisting the over-engorgement of the pulmonary vessels during the first stage of the disease in which this condition of the heart is found to exist. The first case Dr. N. S. Davis reports appeared at first to be an uncomplicated case of catarrhal pneumonia. "No alarming symptoms occurred until the end of the second day, when the exudation began to increase with such rapidity that before the middle of the third day the left lung was completely engorged and dull on percussion from the apex to its base, and there was commencing crepitation in the lower part of the right. Pulse 120 per minute; temperature 103° F. The breathing was oppressed, short, and frequent, with mucous râles rapidly increasing in the larger bronchi. The expectoration was copious, thin, and very bloody. It became evident that before the end of another day, at the same rate of progress, both lungs would be completely filled with exudation and the patient suffocated. Professor Davis directed in consultation 3 grains of ergotin every two hours; also, 2 grains of quinine and $\frac{1}{30}$ grain of strychnine every four hours in addition to 10 minims of tincture of digitalis with aromatic spirit of ammonia alternating with the ergotine. A blister, followed by emollient poultices, was also applied. Under this treatment the aspect of the case was changed in twenty-four hours; the respirations became slower and deeper, the pulse was 108 and more full, the coarse râles were fewer in number, and the bloody expectoration diminished one-half. The patient made an unusually rapid recovery.

The second case presented a similar clinical picture; the treatment was the same, with the exception of the digitalis. It seems, however, that this second case may have received too much of the drug, at least the singular occurrence of a collapsed condition of the circulation and entire cutaneous relaxation, the skin being cold and wet with perspiration, and the pulse hardly perceptible at the wrist, may have been a reaction from the toxic effect of ergot. To restore the tone of the cutaneous vessels and increase the force of the heart's action give digitalis, belladonna, and aromatic spirit of ammonia. When one has used ergot, digitalis, ammonia, quinine, and strychnine to combat a rapidly-spreading pneumonic exudation, it becomes a matter of difficulty to decide to which drug the effect of checking the process is due, and although we are able to sift out the action of ergot in the case of Dr. Davis's admirable account, this objection to the accuracy of the deductions is a plausible one.

In the two cases, one of catarrhal and one of croupous pneumonia, with an exudation filling up the entire left lung, and with coarse moist râles throughout the left lung, ergotole was employed, the clinical chart which follows being a record of the latter. The expectoration in both cases was profuse, thin, and contained an abundance of blood. From the time that the infiltration first became manifest by unmistakable physical signs, with rapid, weak pulse, hurried respiration, and high fever, the patients were put upon ergotole 15 minims in half an ounce of whiskey every two hours. Although a number of other remedies were kept at hand to be used hypodermically, should occasion arise, none them was made use of. These two cases of pneumonia were treated exclusively with ergotole and good nourishment, and both made a speedy recovery. In these cases we are warranted in believing that the ergot in itself had a specific influence over the progress of the exudation, for no such effect could reasonably be attributed to the whiskey which was taken. After the fever had subsided and the pulse

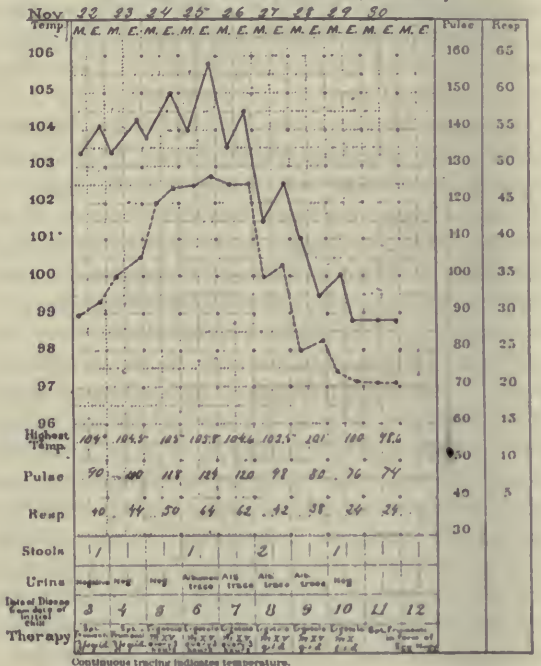
was almost normal, both cases were put on tonic mixtures containing iron, quinine, and strychnine.

Dr. Sunol[1] shows that the action of ergot on unstriped muscular fibre may also be of use in various acute affections of the respiratory apparatus. Thus, in intense acute bronchitis, when there is difficulty of expectoration it serves a useful purpose in emptying the bloodvessels and contracting the bronchial muscles.

Record of Temperature, Pulse, Respirations, etc., of a case of CROUPOUS PNEUMONIA treated with Diet and Ergot exclusively.



Continuous tracing indicates temperature.
Dotted tracing indicates pulse.

Sunol has used ergot successfully in the congestive stages of pneumonia, and very accurately recorded the physiological effects. He states that the breathing becomes slower and easier, the temperature falls, the expectoration becomes free and much diminished in amount. In pulmonary engorgement, he urges that ergot should take the place of bleeding.

It appears from the foregoing, that the indications for the employment of ergot in pneumonia are symptomatic; the special characteristic and tendency must be in each case carefully studied, and the drug promptly administered when we are certain of pathological changes which we know the physiological effects of the drug will effectually counteract.

According to A. L. Loomis,[2] it is still a disputed question whether the bronchial or the pulmonary capillaries are the chief source of pulmonic exudation. The lung-tissue is nourished by the blood in the ramifications of the bronchial arteries, while the capillaries of the pulmonary arteries and veins are the passive media for the interchange of gases. Hence, it has been claimed that the bronchial capillaries only are implicated in the inflammatory process. Virchow has shown that the pneumonic process can be completely established in places where the pulmonic capillaries cannot be traced on account of the plugging of a large branch of the pulmonary artery.[1] He concedes, however, that the capillaries of the pulmonary artery and vein are secondarily actively concerned in the inflammatory process. On the other hand, it has been claimed that in the early stage of the pneumonic process the parts that are supplied by the bronchial capillaries are not reddened or injected as they would be were these vessels primarily concerned in the inflammatory process. It is probable that both sets of vessels are involved, but that at the beginning one set is implicated to a greater degree than the other. We will dwell on this matter to some extent under the heading of hæmoptysis.

During the course of any inflammatory process there is a period when transudates are formed. The swelling which occurs in the inflamed area may be regarded as a macroscopic evidence of the process of transudation. We learn from R. Klemensiewicz[2] that a large number of experimental facts support these assertions. The first stage of pneumonia, in which at times alarmingly rapid transudation occurs, often cannot be differentiated from the symptoms of pulmonary congestion and œdema, and is a process in which the blood plasma, and later on the corpuscular elements of the blood, pass from the interior of the bloodvessels to the surrounding spaces. The difference in the specific gravity of the constituents of the blood and the condensation of the axial part of the blood stream explain, according to Schklarewsky,[3] why the plasma escapes first and the corpuscles later on. During the process of exudation the so-called Poiseull space disappears in the vessels, and the corpuscular elements appear adjacent to the vessel wall.[4]

The vessels are, at the beginning of the transudation, only moderately filled with corpuscles, but as the process goes on the vessels become packed with corpuscles and the velocity of the blood current becomes much slower. Glax and Klemensiewicz have shown that a current is possible and does occur in the artery of an inflamed vessel after complete stagnation has occurred in the capillaries and veins connected with it. This is the only possible ex-

planation for this phenomenon. The liquid constituents find an exit from the interior of the vessels into the space surrounding them by lateral openings which exist in the walls of the vessels themselves. The capillaries possess permeable walls. The permeability of the vascular walls is, however, not confined to the capillaries, for to a greater or less degree the walls of the smaller arteries and veins possess this property of permeability. The permeability of vascular walls varies according to their location; that is, exudation will occur to a greater extent in loose than in dense tissue. The permeability increases in the larger arteries toward the veins and as the blood-pressure decreases. The onset of transudation is coincident with the pathological change in the vessel wall, and it is this change, and not an increase in pressure, which causes the exudation in pneumonia.

We believe that ergot exercises a very decided effect upon the pulmonary vessels.

Transudation has been proved, by a very large number of observers, to depend mainly upon the permeability and elastic distensibility of the blood-vessels.

If the reader will consider these facts for a moment, and then think of the physiological action of ergot, he cannot fail to realize what a powerful agent this drug is in checking inflammatory exudation, as clinical experience has undoubtedly proven it to be in the first stage of pneumonia. If transudation depends upon the permeability and elastic distensibility of the vessels, we know that ergot, by constricting these, can reduce peri-vascular engorgement.

If transudation is associated with increased heart's action, we know that ergot reduces the number of heart-beats.

If the beginning of pneumonic exudation is associated with hurried breathing, we know that ergot reduces the number of respirations per minute.

If transudation is connected with fever, we know that ergot reduces temperature.

If the fever in inflammatory exudations lowers blood-pressure, we know that ergot raises it.

All of these physiological effects directly counteract the main features of the pathological process, and check further transudation, while the lymphatics carry away the exudation that has already occurred.

In the experimental part of this report[1] we did not mention a number of experiments which we undertook with Ludwig Stromuhr, to measure the velocity of the blood-current in the carotid artery of dogs. The velocity of the carotid current in a dog was estimated at 206 mm. in a second. Under ergot—*i. e.*, five minutes after 1.5 c.c. of ergotole in defibrinated blood had been injected into the jugular vein—the estimate of the velocity was 169 mm. in a second. The same fact was established in the case of a cat. We have here an experimental proof that the amount of blood flowing from a bleeding (torn) vessel in a given time will be less after the animal has received ergot. That the reduction was due to ergot, and not to accident, was proved in the dogs after the effect of the drug had subsided. In fifty minutes the velocity of the current in the carotid of the same animal was estimated at 200 mm. in a second; and at this time a second injection of 1.5 c.c. of ergotole, similarly diluted, was made into the jugular vein. The next estimate—taken eight minutes after this injection—showed the velocity reduced to 163 mm. in a second. Hence, we have a right to believe that ergot directly reduces the rate of the blood-flow, probably by reducing the work of the heart and opposing more resistance to the stream by constricting the unstriped muscular fibres in the vessel-walls.

(*To be concluded.*)

[1] See The Medical News, January 31st and February 7th.

A BRIEF REPORT OF FOUR MONTHS' SERVICE IN THE SURGICAL WARDS OF THE PENNSYLVANIA HOSPITAL.[1]

By THOMAS G. MORTON, M.D.,
ONE OF THE ATTENDING SURGEONS.

The following very brief review of the more important surgical work which came under my care at the Pennsylvania Hospital during my term, which represents half of the service, which has just expired (from October 1, 1890, to January 1, 1891, inclusive), may, I trust, be not without interest.

At the very outset, I will state that in all the surgical work aseptic precautions were rigidly observed, as heretofore. In quite a number of cases this was rendered difficult from the fact that patients not infrequently were brought from a distance with their wounds already dressed, perhaps hours before arriving at the hospital. In some instances wounds, which apparently had been carefully dressed, were found, upon examination, to be impregnated with coal-dust or other extraneous matter. In all such cases the rule was observed to reopen, examine, and redress the wounds.

One interesting example of this kind was admitted from the coal regions in November. The patient was a miner, whose thigh was crushed by falling coal. His wounds had been dressed by a neighboring surgeon at the time of the accident, and he

[1] Read before the Philadelphia Academy of Surgery, February, 1891.

was not brought to the hospital until thirty-six hours afterward. The external wound, which was extensive, and had been carefully and tightly sutured, was reopened, when it was found that there had been complete division of all the muscles on the posterior part of the middle of the thigh, exposing the sciatic nerve and the femur; numerous particles of coal and other foreign matter were found in the tissues and elsewhere. The wound was then thoroughly cleansed, and the divided muscles carefully approximated and closely sutured, which was followed by prompt healing, the patient recovering with good flexion and extension.

It is worthy of comment that during this term of service there was not a single case of erysipelas, septicæmia, or tetanus, no secondary hæmorrhage or other complication following any major operation, and but two deaths following operations. One of these occurred after an abdominal section, which will again be referred to; the other fatal result followed an amputation of the thigh, crushed in a railroad accident. On account of extreme shock from the injury and loss of blood from the femoral artery, which had been torn, it was impossible to operate until twenty-four hours after the accident. Death followed from recurring shock.

Amputations and wounds incident to operation or injury invariably healed by first intention; indeed, suppuration occurred only in such cases as perineal section, suprapubic cystotomy, etc., in which the wound could only close by granulation. In one case of perineal section several hæmorrhages occurred, but it was subsequently ascertained that the patient had always been of a markedly hæmorrhagic diathesis. He afterward made a good recovery.

The strength of the mercuric solutions for irrigation was uniformly 1 to 1000, and for the wet dressings 1 to 2000; in case of young children this was reduced to 1 to 2000 and 1 to 4000, respectively.

Whenever possible, the region of operation was cleansed on the previous day, or even earlier, and the parts were carefully protected by towels wrung out of the bichloride solutions. In no case was there toxic effect from the absorption of the bichloride solutions, or irritation from its application, on the body of the patient or hands of the attendants.

As a dusting powder, "aristol" was used almost exclusively; it is probably a germicide, and does not produce irritation, while its freedom from odor is in its favor. It seems to be more efficient and in every way superior to iodoform.

In all cases catgut was used for ligating arteries, for approximating bone-surfaces after resection, etc., for closing and for draining wounds, and even for the drainage after amputations. Rubber drainage-tubes were used in operations in the chest cavity, and glass tubes for the abdominal sections. Silk was employed for suturing the intestines and closing wounds after operation.

In the treatment of "shock" strychnine was administered hypodermically, and gave excellent results, in doses of from $\frac{1}{60}$ to $\frac{1}{30}$ of a grain repeated about every half-hour.

In the treatment of fractures I have nothing new to report. The dressings were always of the most simple kind; the fracture-box, which was often suspended, was used for fractures of the legs; extension with lateral support by the sand-bags for the femur, and after union had occurred moulded pasteboard, silicate of sodium, or plaster dressings were applied. In fractures of the humerus, moulded pasteboard splints were employed externally, the chest-wall being utilized in many cases for the internal splint; the right-angled splint was all that was required in many cases.

Fractures of the lower end of the radius required no special form of splint, the complete and immediate reduction of all displaced fragments making the treatment very simple.

In explanation of the comparatively small number of fractures during a winter term of service, and especially of the small number of the upper extremities, it should be stated that a very large number of fractures coming to the hospital were dressed in the receiving ward, and then sent to the out-department. Only the more serious of such injuries were received in the wards. One hundred and four cases of fracture were taken into the hospital. Of these, sixty-nine were *simple fractures*—sixteen of the femur, and twenty-three of the tibia and fibula, the remaining number included the patella, scapula (one due to muscular violence), ribs, pelvis, vertebræ (spinous processes only), and upper extremities. Thirty-five were compound fractures—six of these involving the femur, five the tibia and fibula, twelve the skull, and twelve the upper extremities.

Operations.—Five compound depressed fractures of the skull required trephining; the wounds closed by immediate union, and without any subsequent symptoms. In trephining, when possible, especially when the scalp wound is of considerable extent, I prefer not to use an anæsthetic.

Of thirteen amputations, three were amputations of the thigh, three of the leg, and seven of the arm, forearm, and foot. All recovered, except one case of thigh amputation, already referred to.

Seven laparotomies were performed.

One case of purulent peritonitis, apparently idiopathic from its rapid course, seems worthy of record.

Emil L., about fifty years of age, living about seventy miles from Philadelphia, had occasional slight attacks of abdominal pain during the pre-

ceding four or five years, but had never had any serious illness. Present attack came on about eight hours before admission. He had been hard at work during the morning, cutting and hauling ice; at noon he rode to his home on a load of ice, and ate heartily of pork and cabbage. Pain came on suddenly, and he took a train for his son's home in Philadelphia. Arriving in great distress, he was brought to the hospital, and was admitted to the medical ward about eight o'clock the same evening. He was not improved by treatment. Toward noon on the following day his temperature had fallen to 97.4°, pulse and respiration increased, and a fatal termination seemed inevitable; sixteen hours after admission the case was transferred to the surgical ward by Dr. Da Costa. An exploratory abdominal incision revealed the presence of purulent peritonitis; the bowels were covered with recent flaky lymph, and the belly-cavity contained pus. The appendix was examined and found normal, and no local cause for the disease could be discovered.

The patient died five hours after the operation. A post-mortem examination could not be obtained.

Two of the cases of abdominal section for removal of the appendix vermiformis seem worthy of record; the first was that of a pericæcal abscess. The history of the case is as follows:

George I., aged thirty years, was admitted May 12, 1890, in a prostrated condition, and with a history of pericæcal inflammation, followed by symptoms indicating perforation of the appendix and abscess.

The attack came on suddenly with pain in the region of the appendix, which was greatly increased by pressure; there were nausea, fever, and constipation. Later, there was a sudden accession of intense pain, with deep swelling, general abdominal tenderness and tympany. The temperature was fluctuating and there were chills and profuse sweating. The skin over the ileo-cæcal region became discolored and somewhat œdematous, but no distinct tumor could be felt at any time, yet there was a hardness of the deep tissues. Such were the conditions on admission. A lateral incision was made directly over the region of the appendix, and a large abscess cavity containing fœtid pus was exposed; careful search failed to discover the appendix, but the surrounding organs were so matted together by adhesions, that further exploration was not deemed prudent. It was supposed that the appendix had been destroyed by the violence of the inflammation, which had probably resulted in gangrene of the organ.

The abscess and abdominal cavity were thoroughly washed and two drainage-tubes were inserted, one of glass to the bottom of the pelvic cavity, the other of rubber into the most dependent part of the abscess cavity.

A rapid recovery followed, but a fistulous opening remained, which now and then discharged excrementitious matter, showing that an opening existed in the intestine, which was probably at the site of the appendix.

In October a second section was made directly in the line of the first operation, for the purpose of closing the fistula. On reaching the cæcum, it was found that all the adhesions which were present at the first operation had been completely removed. The cæcum could be readily manipulated, and was found open, as expected, at the site of the appendix, which had unquestionably sloughed off, leaving a fistula of sufficient size to admit the end of the little finger.

The fistula was closed with nine Lembert sutures. Rapid and perfect recovery followed.

The history of the second case is as follows:

Mrs. E. S., aged forty-six years, was admitted January 5, 1891, with symptoms of appendicitis, which had existed for a week. There had been considerable pain, with elevation of temperature, abdominal distention, constipation, furred tongue, and vomiting. Directly over the ileo-cæcal region a tumor was discovered which was movable and exceedingly painful upon pressure. There had been neither chill nor sweating. The symptoms pointed to irritation or inflammation of the appendix, or of the peri-cæcal region, but not to abscess. A lateral section was made on the eighth day. Upon entering the abdominal cavity, the tumor proved to be an immensely elongated and distended gall-bladder about five inches in length, lying directly over the appendix. A careful examination failed to show the presence of gall-stones. The appendix was found inflamed and thickened but quite free from adhesions. The mesentery and appendix were ligatured and cut away. The stump of the latter was then inverted and invaginated into the cæcal cavity. The peritoneum was brought together over the inverted stump by five Lembert sutures. No drainage-tube was used, and the wound was closed with a few sutures.

The patient left the hospital on the twenty-first day in good condition.

Two cases of brain abscess, one involving the cerebellum and the other one lobe of the cerebrum, are interesting from the fact that neither presented symptoms which are commonly found in such lesions.

Case I.—The patient, thirty-six years of age, was sent from the out-patient department of the Pennsylvania Hospital to the surgical ward, by Dr. Harlan, on account of an aural polypus and purulent otorrhœa. The patient presented no special symptoms during his stay in the hospital; there was only a slight rise of temperature, no chill, and apparently no motor or sensory symptoms. A few days after admission he complained of a general headache, soon became comatose, and never regained consciousness. There were no symptoms at any time indicating an abscess. Dr. Harlan also saw the patient, and agreed with me in this opinion.

The autopsy showed serious disease of the petrous portion of the temporal bone; the inflammation extended from the middle to the internal ear, thence through the internal auditory meatus to the cere-

bellum by continuity, where a large abscess was found.

CASE II.—A man, aged twenty-four years, was admitted to the medical ward. He had been working as a night brakeman on the Reading Railroad until early in the morning of the day that he was brought to the hospital. He went to his bedroom that morning, and was not seen until evening, when he was found unconscious. When brought to the hospital his pulse was slow but regular, pupils equal, respirations full and deep, and limbs rigid, but there was no paralysis.

His companions stated that he had never complained, had always performed his work, and that he had appeared in good health up to the time when he was found unconscious.

The autopsy showed a very large abscess in the anterior lobe of the cerebrum, greatly distended by recent hæmorrhage, which had caused sudden death.

Ten dislocations were treated, of which two were dorsal luxations of the hip, while the others were of the humerus, clavicle, and elbow, the latter in a child, and without fracture.

Of ten gunshot wounds, there were two involving the thigh, in one case the ball passing through the penis and scrotum; four of the arm and leg; and four of the chest-cavity. One of the latter cases died soon after admission from internal hæmorrhage. Nine cases of concussion of the brain recovered.

Of miscellaneous operations there were: 1 suprapubic cystotomy (stone weighed 960 grains), 1 perinephritic abscess (opened and drained), 3 preliminary ligations of the femoral artery, 3 removals of testicles (tuberculous and syphilitic), 4 perineal sections for impermeable stricture.

There were also a number of cases of amputation of breast, removal of bony, fatty, and other tumors; strangulated hernia; repairing of cervix and perineal lacerations; fistula in ano; fissures and hæmorrhoids (the latter were all treated with the ligature); resection of the shaft of the femur, the tibia and fibula, and humerus; opening of deep and superficial abscesses, in the interior of bone and in soft parts; minor plastic operations, and resection of nerve-trunks. Taken collectively, these operations form a wide range of work. In the operative treatment of all the cases, it is gratifying to report that there were but two deaths, already referred to, both of which occurred within twenty-four hours after admission, and both presented almost fatal conditions when admitted.

DISCUSSION.

In discussing this paper, DR. J. EWING MEARS said that among the many cases presented in the report made by Dr. Morton, none possessed greater interest than the one of acute suppurative peritonitis. The history of the case—the exposure to cold after very active exercise, and, possibly, while the skin was wet with perspiration, with the imprudence in diet, as exciting causes—made the diagnosis of idiopathic peritonitis clear. While the evidence afforded by recorded cases shows that this form of peritonitis is rare, the clinical history in the present case is sufficiently distinctive. When the disease has progressed to the stage of suppuration, abdominal incision, combined with antiseptic irrigation and drainage, is the method of treatment which should be employed.

DR. J. H. PACKARD said: "My attention has lately been called to the fact that in some places, especially on the Continent of Europe, the chisel is preferred to the trephine in opening the skull. I would like to know if any of the gentlemen present have seen the chisel used in this way, and whether it is different from the one used in ordinary surgical operations?"

DR. JOHN B. DEAVER: "Dr. Morton mentions a case in which a lacerated wound of the leg was brought into the hospital in a septic condition. This is one of the troubles hospital surgeons have to contend with. The great difficulty met with in the treatment of compound fractures is that the wound is septic at the time of admission. Our ambulances should be so prepared with antiseptic appliances that, from the time the ambulance-surgeon arrives at the scene of the accident until the case reaches the hospital, the wound could be under antiseptic treatment. Our patrol system should also be so arranged that antiseptic measures could be carried out. I recall one case of compound fracture of the forearm in which septic osteomyelitis followed, and in which amputation was eventually required. Had the wound been rendered aseptic at once, there is a bare possibility that so radical an operation as amputation might have been avoided. I think it would be well if some concerted action were taken by the Fellows of the Academy relative to this point.

"Dr. Morton reports a case of rather severe hæmorrhage following perineal section. I recall a similar case which occurred during my hospital service, some two years ago. I operated for an impermeable stricture involving the membranous urethra. Consecutive hæmorrhage necessitated packing the wound. Twelve hours after the operation, I was called on account of symptoms of concealed bleeding. I found a tumor in the hypogastrium, which proved to be a blood-clot. The clot suppurated and caused septicæmia, from which the patient did not recover for three months. Here there was a decided family history of the hæmorrhagic diathesis.

"I would ask Dr. Morton how he treats fractures of the patella. Recently, I was asked to see a warm personal friend—a physician—who had fractured the patella of the right side. He also had an ununited fracture of the patella of the left side. He had sent for a surgeon, who employed a posterior splint. He asked me what I would have done under such circumstances. I declined to say anything about the case, except in consultation with the attending surgeon. A meeting was appointed, but the surgeon did not appear. I then felt at liberty to tell my friend that if it were my patella I would have it wired or have Malgaigne's hooks applied. When the surgeon arrived, he stated that he disapproved of such treatment, and upon the following day brought with him a letter from a prominent surgeon condemning both of

these operations. Dr. Phelps, of New York, has reported forty-three cases of fracture of the patella treated successfully by wiring. I prefer to treat these fractures with Malgaigne's hooks. It is claimed that the use of the hooks converts the fracture into a compound one. This is a mistake; but, even were it so, it would make but little difference, if antiseptic surgery amounts to anything."

Dr. Morton: "I have not used Malgaigne's hooks for years. In all suitable cases I open the joint by a vertical incision, and after drilling the fragments in at least two places, make close approximation with large size catgut. In every case so treated there has been apparently good bone union.

"One very serious objection to Malgaigne's hooks is, that very commonly torn portions of the ligamentous tissue after fracture fall in between the upper and lower fragments, and prevent bony union."

Dr. Mears: "When this subject was under discussion in the Academy some time ago, I stated that I thought the time had come when, in considering fracture of the sesamoid bone due to muscular contraction, the nomenclature could be changed so as to express more accurately the condition present, and thus lead to more rational methods of treatment. In fracture due to muscular action the structure essentially involved is the ligament, and as the result of the vulnerating force there is a rupture of the fibres of the ligament, accompanied by stretching of the unbroken fibres. In these cases, treatment by the former method, which had for its object apposition of the fragments of the bone, resulted in the infolding of the lacerated and stretched fibres so that they either rested between the ends of the fragments or over them. As the process of repair takes place the folds become attached to each other by plastic material, which is not very great in quantity. If the patient is confined at rest for a period of two, three, or four months, the union may become firm enough to prevent, under ordinary force, the separation of these folds, and with them the bony fragments. In fracture due to direct violence, there is contusion of the ligamentous fibres with fracture of the bone, but not rupture of the fibres of the ligament, and hence there is little or no separation of the fragments. The first condition may be properly designated as a rupture of the ligament with fracture of the bone; the second as a contusion of the structure with fracture. The treatment in the first condition is manifestly the same as that practised in case of rupture of a tendon anywhere, viz.: Exposure of the part by an incision, removal by the knife of the lacerated and stretched fibres, and suture of the divided ends of the ligament. If this is done thoroughly, it matters little what takes place between the ends of the bony fragments, as the bone originally does not contribute in any way to the strength of the ligament. In the second condition, in which the ligament is simply contused with fracture of the bone, rest upon a splint will give a successful result, as separation of the fragments cannot occur with the ligament untorn."

IODOFORM-POISONING.

An Addition to its Literature, with the Report of Four New Cases.

By RUDOLPH E. GERLACH, M.D.,
EX-RESIDENT SURGEON TO THE GERMAN HOSPITAL, PHILADELPHIA.

But few cases of affections of the skin and subcutaneous tissue following the surgical use of iodoform have been reported. It is, therefore, remarkable that four such cases have come under the observation of the writer, three within the last eighteen months. It will be seen, too, that three of the cases had some interesting phenomena in common.

Case I.—Mrs. K., aged forty-five years; plethoric; was treated for a varicose ulcer above the ankle. The skin around the ulcer having become macerated by the use of adhesive strips, about two drachms of iodoform ointment (one drachm to the ounce of lard) were smeared on lint and applied under an elastic-roller bandage in the morning. A few hours afterward the leg began to itch. In the afternoon intense burning pain in addition to the itching caused the patient to remove the bandage. Her whole leg, from the instep to about two inches below the knee, was inflamed, swollen, and covered with blebs which had in part broken and discharged a serous fluid. The itching soon became general but there was no spread of the eruption, although free perspiration came on. Twenty-four hours after the application the patient noticed a sensation of tension and stiffness in the skin of the face. Œdema of the eyelids soon appeared and was followed by a rapidly-developing swelling of the face and temples, including the ears. This swelling was not inflammatory, or sensitive, but seemed quite resisting to the finger. On the second day a papular eczema developed on both forearms, the arms, the neck, and the upper third of the chest and back. This eruption on the forearms was preceded by swelling, and after the complete disappearance of the latter, became very widespread. On the sixth day the swelling of the face rapidly grew worse, and on the eighth day the patient was almost completely unable to see on account of the mechanical closure of the eyelids. No fever had existed, and her general condition was good. There was no headache and no gastric disturbance, but great languor existed.

The urine was alkaline, had a specific gravity of 1010, and was very light-colored, but not voided in excessive quantities. It contained no albumin.

The patient had so far been treated by saline purges. On the eighth day ten grains of calomel and five grains of bicarbonate of sodium were given in one dose. On the following day the swelling had greatly decreased, and after another twenty-four hours the face had entirely changed. The swelling had subsided to a slightly and uniformly raised, indurated, red surface, extending from the eyebrows over the whole of the face, and laterally over the temples and ears. It had sharply-defined, smooth outlines, and at first sight resembled erysipelas.

There was, however, only a little inflammatory redness, no constitutional symptoms, no pain, and no tenderness, but an annoying itching was persistent.

On the tenth day the appearance was that of a papular eczema, showing at some places a tendency to scale. The outlines had lost their sharp contour.

After two weeks the swelling had completely subsided, but some eczema of the face and forearms persisted for four weeks.

The healing of the ulcer was remarkably rapid. The induration which had proved so obstinate was absorbed, healthy granulations started up, and in a week's time the ulcer had completely healed and the surrounding skin was regenerated.

Interesting in this connection is the statement made by the patient, that eight years ago, while treated in a New York hospital for varicose ulcers, a similar train of symptoms, only more severe, occurred after the use of a yellow salve of the same odor as the iodoform ointment used on this occasion. The patient was sick in bed for several weeks, and, to quiet her pain, had to be kept under morphine for several days.

She also states that the appearance of her face, and her sensations were the same at that time, and that the hospital physicians had completely isolated her.

The iodoform ointment used on this occasion was freshly prepared and had been applied on other patients without bad results.

The following case, resembling the last in the cutaneous phenomena, was under the observation of the writer in the German Hospital of Philadelphia, in the fall of 1889, under the care of Dr. John B. Deaver, who has detailed the history in his article on secondary bone-implantation, in THE MEDICAL NEWS of December 28, 1889.

CASE II.—A. H. had for some time suffered from necrosis of the lower third of the femur. The diseased portion was removed, a large cavity resulting, which healed slowly. To hasten the process, implantation of decalcified, prepared bone-chips was practised. During the operation considerable iodoform was used. On the evening of the operation the patient had some fever, a rapid, weak pulse, and delirium characterized by frightful hallucinations. She recognized, however, every person about her. The patient was somewhat hysterical.

There was swelling of the face within twenty-four hours, especially around the eyes, which continued for several days and disappeared with the fever and delirium.

The healing of the wound was in no way unfavorably influenced, and it was always aseptic. Dr. Deaver attributes the phenomena to the influence of the iodoform.

The third case occurred in the person of the writer.

CASE III.—After a hip-joint resection, which, on account of a sponge sewed up in the wound by mistake, left a discharging sinus, a periosteal abscess formed on the left foot, which was laid open to the extent of three inches and packed with iodoform-gauze. The same night the face and hands began to swell and to ache and violent gastric pain set in, with nausea and vomiting, which continued for forty-eight hours. The iodoform-gauze was removed twenty-four hours after the application.

There were intense headache and languor. The swelling of the face and hands, at the end of forty-eight hours, had extended nearly to the elbows, and increased to such an extent that the hands were literally two large, unshapely masses of flesh, and the wrist-joints obliterated. A week subsequently the swelling had subsided.

Iodoform had, after previous operations, been freely used without evil consequences.

CASE IV.—The fourth case, to which I shall only allude, was M. B., a patient in the German Hospital during the winter of 1889-90. The anterior tibial nerve was resected on the dorsum of the foot, on account of neuralgia of the great toe, and an iodoform dressing applied. Acute dermatitis of the whole foot and part of the leg at once developed, with burning and scalding pain, the formation of blebs, and a profuse serous exudation. Later an iodoform dressing was again tried with the same result. No general or other local symptoms were noticed.

The features common to the first three cases are the solid tumefaction of the face, and, in two of them, the implication of both the hands and forearms. The swelling of the face was in all three cases urticaria-like.

The eruption on the arms in the first case was eczematous, and preceded by swelling, while in the third case no eruption appeared with the disappearance of the swelling.

In the literature on the subject the writer has found the following cases:

Urticaria developing on the second day after an application of iodoform powder to a small granulating surface left after a compound fracture of the radius and ulna, is reported by Powell[1] as the first case in his large experience. Wheals covered the face, neck, sternum, and back, and the whole forearm was covered with nodules. The wound healed rapidly.

The cases of acute eczema after the application of iodoform are reported by Fifield[2] and Campbell Pope.[3] The former used a small quantity of iodoform in powder on two successive days on an ecthymatous ulcerated surface of the scalp. Eczema, with a profuse serous discharge, developed on the second day. Two days later the head, face, and neck were enormously swollen, and the eyelids puffed to such a degree as to interfere with vision. There was but little systemic disturbance. The pulse was rapid.

Klomann[4] used from 30 to 40 grains of iodoform

[1] St. Louis Medical and Surgical Journal, vol. lvi., 1889.
[2] Boston Medical and Surgical Journal, March 16, 1882.
[3] Lancet, London, 1889, vol. i. p. 681.
[4] Maryland Medical Journal, 1889, vol. xxi. p. 404.

in powder on a rather extensive leg-ulcer. A few hours afterward acute dermatitis of the whole leg, and bleb-formation, developed with severe scalding and burning pain. The legs swelled, and also the hands, the latter to such a degree as to prevent flexion of the fingers. Constitutional depression was absent.

Barois's case[1] differs from the cases already cited in that an eruption appeared after repeated injections of an ethereal solution of iodoform two months previously. The eruption was urticaria-like, and located, as usual, on the arms, breast, and shoulders.

In addition to these peripheral cutaneous affections, a number of disturbances of the central nervous apparatus have been published, and which may be grouped together.

Most of these observations were made in France and Germany. They included all conditions, from simple active delirium to acute mania; and also mental depression, melancholia, and hypochondriasis, with or without sleepiness and stupor. Fever and gastro-intestinal disorders are either absent or present in variable degrees.

Koenig makes a distinction between a form resembling meningitis and a comatose form. To the former class belong cases of acute mania reported by Langenbeck,[2] of which several are said to have died.

A good example of the second group is the case published by Seeligmüller,[3] in which a moderate quantity of the powder was used on extensive surfaces. In this case the symptoms were, melancholia, hypochondriasis, delirium, with delusions, weakness of memory, cardiac weakness, headache, and somnolence.

Casius's[4] two cases of iodoform-poisoning, resembling meningitis in the cerebral and gastro-intestinal symptoms, but not in the temperature (which was only slightly elevated), partake of the characteristics of both groups, with a predominance of the symptoms of the former. Both cases were tuberculous.

Shere, of Hamburg,[5] describes six classes of cases as follows:

1. High fever, without other phenomena.

2. Fever, with mild gastro-intestinal irritation, depression of spirits, and rapid pulse. Recovery almost invariable.

3. Very rapid, soft pulse, from 150 to 180; no fever; great danger.

4. Very rapid pulse, with high fever; death almost invariable.

5. After severe operations, rapid collapse and death.

6. A form resembling meningitis: somnolence, deepening into stupor; pupils fixed in myosis.

The writer has not seen the original article, and, therefore, does not know what quantities of iodoform were used; but, as the cases occurred during the time of the very free use of iodoform in Germany, he assumes that they were large. Furthermore, it seems not improbable that the severity of the operations tended to produce the fatal result in the cases of Group 5, while the cases in Groups 1 and 4 resemble the condition seen after wound-infection.

A fatal case is reported by Langenstein, due to the use of one drachm,[1] and by Czerny after one and a half drachms.[2] "In the first of these the cause of death seemed doubtful."

Recently, a fatal case of iodoform-poisoning was reported by Barois in the *Archives de Médecine et de Pharmacie Militaires*, No. 8, 1890.[3] In this case the symptoms were mainly cerebral, and the patient died in coma on the ninth day. The iodoform was injected in ethereal solution into a cold abscess beneath the pectoral muscle, nearly a drachm being used.

Barois also gives a review of the reports of forty-two fatal cases. His grouping is similar to that of Koenig.[4]

Of the fatal cases, thirteen occurred after amputation of the breast. The disease necessitating the operation is not mentioned in all cases, but whenever noted it was cancer. The very large percentage of cancerous, tuberculous, or scrofulous individuals among the fatal cases arranged in tabular form, is striking. Of the forty-two cases, such a diathesis or cachexia appears in thirty-seven. The others were as follows:

1. Ovariotomy. (Disease not given.)

2. Removal of the tongue. (Primary disease not mentioned.)

3. Amputation of a leg.

4. Laparotomy. (Myoma uteri.)

5. Vaginal hysterectomy. (Disease not mentioned.)

Langenbeck's[5] experience, as given by him before the Eleventh Surgical Congress, Berlin, 1882, was that he had seen no evil consequences when he used iodoform cautiously. Eckelmann[6] also finds the

moderate use of iodoform harmless in the surgery of the insane.

It must further be taken into consideration that psychoses at times develop in immediate consequence of operations. Thus, v. Frankl-Hockwart reports thirty-one cases of psychosis following operations on the eye.[1]

The writer himself has seen a case of acute mania following an oöphorectomy during his residentship in the German Hospital.

It is generally accepted that the liberation of iodine, and the action of the latter on the nervous centres and internal organs, are accountable for the grave phenomena and fatal terminations of iodoform-toxæmia. It is also known that various skin eruptions are one of the symptoms of iodism. The use of iodine internally for some time is necessary to produce them, while one of the most striking features of iodoform-poisoning from dressings is their prompt appearance.

Idiosyncrasy must explain why large amounts are so often borne with immunity, while in comparatively few cases under similar circumstances death is caused by small amounts—as little as 45 grains in Barois's case.

Although, as stated by Barois, danger in poisoning depends in part on the form of application and the locality, yet the same mode of application in the same localities is by no means always followed by the same result. It seems that the cause must be looked for in conditions which favor the decomposition of the iodoform and the formation of albuminate of iodine. De Ruyter (quoted in Dr. H. C. Wood's work on therapeutics, 7th edition, page 540) showed that iodoform is decomposed by blood, serum and other organic fluids in which microörganisms are growing, and apparently proved that the decomposition is produced by the ptomaïnes developed by the growing organisms.

If this be true, the danger of the toxic effects of iodoform-application depends on the presence on absorbing surfaces of an organic fluid, as blood or serum, or of ptomaïnes. Whether these be the outcome of bacteriological life or of direct chemical changes seems indifferent.

From the foregoing facts it would appear that:

1. Iodoform-toxæmia, after external application to wounds or ulcerating surfaces, manifests itself in one or more of the following clinical forms, viz.: lesions of the skin and subcutaneous tissue, gastro-intestinal irritation and disturbances of the nervous system, either psychical, thermal, or cardiac in their manifestations.

2. Very small doses do not lead to grave intoxication, though even the most trifling doses may produce annoying skin symptoms.

3. The uticaria-like eruptions or eczematous or simple dermatitis with profuse serous discharge resemble each other in their distribution.

4. All forms of iodoform-poisoning have the common features of rapid development and slow disappearance.

5. In none of these cases was the repair of the wound impaired, but, on the contrary, in some rapid improvement was striking.

6. Some apparently normal individuals are by idiosyncrasy predisposed to iodoform-toxæmia.

7. The fatal cases so far reported show that tuberculous, scrofulous, or cachectic individuals are most exposed to danger, a fact which is well illustrated by the writer's third case of iodoform-poisoning, which occurred after chronic suppuration, while large quantities of iodoform had been used with immunity before the existence of the latter.

8. These clinical facts seem to harmonize with de Ruyter's experimental results, according to which the danger of iodoform-poisoning depends on the presence of organic fluids and ptomaïnes on absorbing surfaces, under the action of which albuminates of iodine are formed, which are subsequently absorbed.

9. The danger of poisoning also depends in large part upon the form of application, that by ethereal solution having proved most virulent, and also, it seems, upon the locality to which it is applied and the extent of denuded surface.

10. Though iodoform is extensively used in specific inflammations, no case of iodoform-poisoning belonging to this group is reported, and therefore it seems not unlikely that immunity exists in syphilitic individuals.

After this article was completed the writer's attention was called by Dr. H. A. Hare to five cases reported[1] by Charles Audry, of iodoform-poisoning following tamponing of the peritoneum after Mikulicz's method. A considerable amount of iodoform was used in each case. In four cases the symptoms were slight, consisting mainly of elevation of temperature, without local or general signs of infection, gastric irritation, and a peculiar metallic taste (*signe de l'argent de Poncet*). Iodoform was discovered in the saliva in each case. The only fatal case was cachectic. An enormous ovarian cyst was removed. Fatty heart and kidneys are supposed to have existed. Iodoform-gauze was used for tamponing. The patient died from septicæmia and iodoform-toxæmia, the former being the immediate cause of death, but the symptoms of the latter being marked.

This is one more fatal case of iodoform-toxæmia

[1] Jahrbuch für Psychol., ix. p. 15, 182. Referred to in Neurol. Centralbl., March 15, 1890.

[1] Lyon Médical, November 16, 1890.

in a cachectic individual. In favor of the theory based on de Ruyter's experiments is also the presence of considerable exudate in the serous sac. On the other hand, it illustrates the importance of excluding septicæmia as a *causa exitus lethalis*, and also the importance of an examination of the kidneys prior to the application of iodoform. In all cases the symptoms supposed to be due to the iodoform developed promptly.

Audry also found that septic symptoms are most likely to develop after the removal of tampons which were firmly packed and adherent. The explanation given by Sänger is adopted, namely, that in the stretching of the gauze strips, part of their contents are squeezed into the peritoneal cavity.

MEDICAL PROGRESS.

Chronic Bronchitis. — *L'Union Médicale* recommends the following pill for chronic catarrhal bronchitis:

℞.—Turpentine } . . of each ½ drachm.
Tar }
Balsam of Peru . . . 1½ drachms.
Benzoate of sodium, a sufficient quantity to make 80 pills.

Two of these pills may be given three times a day, in cases in which there is marked catarrhal exudation into the bronchial tubes.

Treatment of Excessive Sweating.—KAPOSI is said to recommend the following treatment in cases of excessive sweating.

℞.—Powdered tannic acid . . 75 grains.
Alcohol . . . . . 6 grammes.

This is to be made into solution and employed with friction several times a day, in cases of excessive sweating of the axillæ, the skin being afterward covered with pulverized talc. In excessive sweating of the feet it may be useful to employ the powdered talc, powdered starch, or lycopodium with powdered almonds. It is also sometimes useful to resort to washing the parts with alcohol. The patient must be warned not to rub the feet with glycerin or ointments.

Treatment of Senile Pruritus.—In the treatment of senile pruritus BESNIER employs the following solution:

℞.—Carbolic acid . . . . 1 drachm.
Vinegar . . . . . 8 ounces.

This is to be applied as a lotion to the surface which is affected, after having been mixed with from 1 to 2 pints of hot water. Afterward the parts are to be covered with a powder composed as follows:

℞.—Salicylate of bismuth . . . 6 drachms.
Powdered starch . . . 3 ounces.

Or salicylic acid may be employed in place of the salicylate of bismuth, with twice the amount of powdered starch, namely, 6 ounces.

Treatment of Intercostal Neuralgia. — MENARD treats intercostal neuralgia by applying a blister over the painful spot, by painting the part with iodine, or by the use of hot and cold douches. At the same time, if the pain is severe, he administers small doses of opium, or even hypodermics of morphine. Sometimes atropine or chloroform may be needed, and frequently soothing liniments have to be applied. The causes of intercostal neuralgia are numerous, and the condition which provokes the pain must be discovered and removed. If it is due to anæmia, Menard advises a course of baths, accompanied by the use of one of the preparations of iron. On the other hand, if the neuralgia be due to rheumatism, the salicylates, antipyrine, or diaphoresis must be resorted to; and if the case is a chronic one, sulphur, alkaline, or thermal baths should be adopted. Venesection, however, in the majority of cases gives excellent results. In other instances, iodine ointment applied to the walls of the chest, protecting the clothing by means of an adhesive plaster, seems to do great good.

The Treatment of Purpura.—If purpura is accompanied by hæmorrhages, the physician should resort to the use of such drugs as ergot or Monsel's solution. On the other hand, if it depends upon scorbutus, the best treatment is the employment of the juice of lemons or citrons, and the maintenance of a vegetable diet. In those cases which are due to blood-poisoning, the physician should administer tonics and quinine to combat the fever. The nourishment should be liquid, and chiefly composed of milk, thin soups, with a little wine or rum. In cachectic purpura the anæmia is to be cured by the methods usually employed for this purpose. If the disease invades the lower extremities, the patient should be forbidden to walk about, as this tends to an increase in the hæmorrhagic exudate.

Mixture for Catarrhal Jaundice.—

℞.—Powdered rhubarb . . . 7 grains.
Distilled water . . . . 6 ounces.

Make into an infusion, filter, and add bicarbonate of sodium, 2½ drachms, and syrup of peppermint, 5 drachms. Of this, give a dessertspoonful every two hours.

A Mixture for Hæmoptysis.—BAMBERGER employs the following mixture in hæmoptysis:

℞.—Turpentine . . . . 1 drachm.
Oil of sweet almonds . . 1 "
Mucilage of acacia . . . 4 drachms.
Simple syrup . . . . 4 "
Distilled water . . . . 5 ounces.

One teaspoonful of this mixture may be given every half-hour.

Lemonade-wine.—DUJARDIN-BEAUMETZ, in the *Bulletin Général de Thérapeutique*, January, 1891, recommends the following drink in typhoid fever and other febrile states:

℞.—Red wine . . . . . ½ pint.
Tartaric acid . . . . 2 drachms.
Water . . . . . 1½ pints.

Or, if more wine is desired, equal parts of wine and water may be used. For those who prefer a white to a red wine, the white wine may be substituted.

The Treatment of Syphilitic Vegetations of the Genitals.—The following prescription may be employed for the removal of syphilitic condylomata. BOCKART, under the name of "lead-caustic," uses:

℞.—Oxide of lead . . . . . 4 grains.
Saturated solution of caustic potash at 100° . . . . . 2 drachms.
Mix and label, "For external use."

This mixture is to be applied to the vegetations by means of a small glass rod or stick, and immediately after its application a small tampon is to be applied over the spot. After the mixture has been in contact with the vegetation for five minutes, it will be noticed that the mass has the consistency of mucus, and is removed without difficulty. The spot which remains should be treated by a powder of iodoform.

Intra-uterine Antisepsis.—The following prescriptions taken from *La Tribune Médicale* have been collected by COUTURIER from the methods of various gynecologists and obstetricians in France and Germany.

DOLÉRIS uses a mixture composed of

℞.—Creasote . . . . . 20 parts.
Glycerin . . . . . 60 "

BUDIN one of

℞.—Creasote . . . . . 15 parts.
Glycerin . . . . . 50 "

When creasote is not used ROUX and SCHNELL use an emulsion of iodoform made by adding 15 parts of iodoform to 30 parts of glycerin, or in other cases they use the following:

℞.—Iodoform . . . . . 50 parts.
Glycerin . . . . . 40 "
Water . . . . . 10 "
Gum tragacanth . . . 1 part.

In other instances,

℞.—Iodoform . . . . . 2 parts.
Gum tragacanth . . . 6 "
Water . . . . . 10 "

PERAIRE uses,

℞.—Powdered iodoform . . . 10 parts.
Gum tragacanth . . . 1 part.

Glycerin and water, a sufficient quantity to make a suppository.

SPAETH, of Vienna, is said to use suppositories composed of the following materials:

℞.—Powdered iodoform . . . 20 parts.
Gum arabic . . . . 2 "
Glycerin . . . . . 2 "
Powdered starch . . . 2 "

The Treatment of Hepatic Colic and Catarrhal Jaundice with Calomel.—ZACHARIINE, Professor of Clinical Therapeutics at Moscow, has published some remarkably favorable results which he has obtained in the treatment of hypertrophic cirrhosis of the liver and grave cases of hepatic colic accompanied by fever by the administration of fractional doses of calomel. The calomel is to be given in the dose of one-half grain every hour until five or six doses have been taken, and after this every two hours until the characteristic purging produced by calomel appears. If the calomel does not act it is necessary to follow it by a saline or a tablespoonful of castor oil. It is also useful for the patient to use frequently a gargle of chlorate of potassium, in order to avoid the appearance of mercurial stomatitis. This gargle should be continued for some days after the calomel has been stopped. The influence of this treatment is said to be felt almost immediately, and causes very considerable amelioration of the symptoms. The pain, the fever, and the dyspeptic symptoms disappear, and the urine in catarrhal jaundice becomes clear. Alkaline mineral waters may now be given with advantage. In one case of peculiarly severe hepatic colic, Zachariine was obliged to administer calomel in this way on ten different occasions in the space of two months before a cure was obtained.

Night-sweats.—The following prescriptions for the relief of night-sweats are published in the *Revue Général de Clinique et de Thérapeutique:*

℞.—Sulphate or tannate of quinine . 15 grains.
Powdered ergot . . . . 30 "

Divide into four powders and take two or three in the course of the day. This prescription is also valuable in cases having a tendency to hæmoptysis.

Or,

℞.—Powdered agaricine . . 1 drachm.

Make into four powders and take one powder at night.

℞.—Powdered agaricine . . 1 drachm.
Powdered belladonna root . 7 grains.

Divide into four powders, take one powder at night.

℞.—Powdered agaricine . . 1 drachm.
Tannin . . . . . 1 "

Make into four powders and take one to two powders a day.

Prescription of Chloralamide.—GALIANA recommends the following prescription when using chloralamide:

℞.—Chloralamide . . . 45 grains.
Dilute hydrochloric acid 5 parts.
Distilled water . . . 2 ounces.
Syrup of raspberry . 2½ drachms.

One-half of this amount may be given. This may be divided into four doses, one of which may be given every four hours. For rectal injection he recommends:

℞.—Chloralamide . . . 30 grains.
Dilute hydrochloric acid . 2 drops.
Distilled water . . . 3 ounces.

Or the chloralamide may be dissolved in an infusion of tea to which should be added a considerable quantity of sugar.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE MEDICO-LEGAL VALUE OF THE GONOCOCCUS.

SINCE the discovery of the gonococcus, and since its general acceptance by the medical profession as a means of differentiation between specific and non-specific blennorrhœa, hopes have been entertained that it might prove of value in medico-legal cases, especially in those instances of vulvo-vaginitis occurring in children, and often giving rise to suspicions of criminal practice. Neisser, Lober, and Kratter all assert very positively that by the aid of the microscope they can determine without question whether the vaginal discharge is gonorrhœal, dependent upon impure contact, or whether it is non-specific, in which case it may be evoked by any one of a large number of irritants.

VIBERT and BORDAS (*La Médecine Moderne*, November 13, 1890) point out that to be of value in legal medicine the proof must be absolute, and that probabilities are of little avail. The vagina contains, even in health, a vast number of microörganisms. If the secretion of an acute vaginitis occurring in the person of a little girl is examined diplococci presenting all the characteristics of the gonococcus are usually observed.

In those cases examined by the authors the cause of inflammation was purely traumatic, and according to the evidence it was scarcely possible that gonorrhœal pus had come into contact with the mucous membranes. The discharge of these cases contained diplococci resembling in every respect gonococci. From four cases pure cultures of this microörganism were obtained, in the remainder there were other varieties. The diplococci were found always in the interior of the pus-corpuscles, and were very abundant. In form, in dimensions, in position, in grouping, in habitat, and in reaction to staining-fluids, these microörganisms were identical with gonococci.

It is well known that in the Gram method the aniline stain affects all microörganisms likely to be found in blennorrhœal pus excepting the gonococci; hence, when a preparation previously colored is washed for some minutes in Gram's solution and is then dehydrated in alcohol the gonococci are completely decolorized. The diplococci of non-gonorrhœal pus act in the same manner.

Other authors and especially Bumm have asserted that there are microörganisms which cannot be distinguished either morphologically or by staining-methods from the gonococcus.

It would seem from the present evidence that the results of microscopical examination of vulvo-vaginal discharges are not sufficiently conclusive to warrant a positive statement either for or against impure contact.

THE TREATMENT OF CHRONIC PERIMETRITIS AND PARAMETRITIS.

DR. SAVAIL (*Revue Obstétricale et Gynécologique*, September, 1890), in advocating the treatment of chronic perimetritis and parametritis by warm sulphur baths, offers the following theory: Perimetritis, secondary to chronic catarrh and hyperæmia, depends in the beginning on a permanent lesion of the epithelium lining the uterus, tubes, and follicles of the ovaries, which, in its whole extent, is derived from the germinal epithelium, and presents, with the exception that the cilia are absent in the cylindrical epithelium of the follicles, the same general type.

In support of his treatment the writer alludes, first, to the excretion of sulphur by the epithelium of the air-cells, proved by the early demonstrations of Bouchardat, in which the exhalations from patients under sulphur treatment cause the surface of a lead plate to turn black. He then refers to the theory of Bergeon in establishing the beneficial action of sulphur, during its excretion, on the pul-

monary epithelium; and concurs in the opinion of Küss, who, in his experiments on the intestinal absorption of sulphur contained in the bile, demonstrates the importance of this substance in the reconstruction of the epithelium. He attributes to sulphur a double action on the epithelium—antiseptic and reparative: antiseptic—in neutralizing toxic alkaloids of bacterial origin; reparative—in reëstablishing the physiological resistance of the cells; or, in other words, in exerting a *vivifying* influence on the germinating layer of the epithelium. Thus, in chronic perimetritis, the treatment owes its efficiency to the chemical, as well as the thermal, action of the sulphur baths; in parametritis the latter element plays the more important *rôle*, in stimulating, by means of warm baths, the peripheral circulation, and by exciting, by means of warm sulphur douches, the pelvic circulation.

He is particular to place the altered hygienic and climatic conditions of the patients, their physical and moral repose, and the mode of employing the waters under the head of auxiliaries, but it is a question whether in this he does not claim for his method an undue advantage over other baths. However this may be, the cases which he reports speak for the success of the treatment, and the importance of his communication is manifest: First, because he attaches a clinical importance to the primary pathological lesion; and secondly, because he brings to notice the advantages of general treatment in such disorders.

No doubt the advocates of massage would be unwilling to admit that the foundations which they claim for their mode of treatment, namely, stimulation of the pelvic circulation, and restoration to the lymphatics and nerves of the pelvis their proper function, are not claimed with equal justice by the hydropathist.

In our opinion, however, the hydropathic treatment accomplishes the results attributable to massage by milder procedures, and by measures better directed toward the general improvement of the patient, and, therefore, offers the greater advantages.

ABDOMINAL PAIN AS A SYMPTOM OF SLOW HÆMORRHAGE INTO THE PERICARDIUM.

ABDOMINAL pain is certainly not frequently present in cases of slow hæmorrhage into the pericardial cavity, for it is entirely omitted in the accounts of this condition given by most authorities. It is, therefore, interesting to observe that Dr. NAISMITH, of Scotland, has reported four cases of this nature—three in the *Lancet*, July 11, 1885, and the fourth in the *Lancet*, November 9, 1889. In all of these cases the ordinary symptoms of hæmorrhage into the pericardial sac were either absent or quite overshadowed by the abdominal pain.

In the first case, a man of forty-eight years was found lying on the ground much exhausted, and complaining of pain in the region of the abdomen. His statement was that he had felt something give way in his chest. His pulse was feeble, there was a sense of constriction in the chest with slight dyspnœa, but the abdominal pain was so marked (although there seemed to be no disease of the abdomen) that opiates and poultices were used. In six hours he died, rather suddenly. At the post-mortem examination the aorta was found atheromatous, the pericardium was distended with clots and fluid blood, and there was an aneurism as large as a hen's egg of the ascending portion of the aortic arch, which had opened by a small aperture into the pericardium. The heart was pale, flabby, and friable, but its valves were competent, and there was no disease of the abdominal organs found.

In the second case, a man forty-five years old received a blow on the chest. Though complaining of pain in the chest, he was able to walk home, and on arrival seemed about as usual. In an hour he went to bed suffering from pain in his abdomen. A physician applied poultices to the epigastric and umbilical regions, where the pain was most severe. The patient became worse, and died in eight hours. On post-mortem examination no disease was found in the abdomen. The pericardium was distended with clots and blood, and a rupture was found in the wall of the right auricle a fourth of an inch in length, very narrow, and made valvular by a clot. The aorta and heart were somewhat degenerated; the other organs were normal.

In the third case, a man of twenty-five years was found on his back by the roadside, conscious, but extremely weak, and his clothing soaked with blood. There was a knife-cut over the heart an inch in length. He did not think that the wound was fatal, but asked to have his trousers loosened, as he felt great pain in his abdomen. He died while being carried to the hospital, six hours after the injury. At the post-mortem examination the cut was found to have penetrated the pericardium, which was full of clots and blood, and to have passed through the

wall of the left ventricle. All the other organs appeared to be normal.

In the last case, a female laborer forty-eight years of age, who had had occasional attacks of dyspnœa and pain in the chest, became suddenly very ill, with vomiting and severe abdominal pain. When seen by a physician on the following day she was in bed and suffering from agonizing pain in the epigastrium, but not in the heart. This pain had been constant since the onset of her illness. No disturbance of respiration was noticed. In this case also the treatment was directed to supposed disease of the abdomen. She died twenty-six hours after the accident.

At the autopsy the pericardium was found livid and tensely distended with clots and blood. There was an aneurism of the aorta the size of a small egg, which opened by a minute orifice into the pericardium. The aorta was atheromatous; the heart-walls were soft and friable. It was supposed that rupture had occurred several hours before death. No other signs of disease were found.

All these cases occurred in medico-legal practice in Scotland, and are to be accepted as reliable. No attempt was made to minimize the other symptoms, nor does the writer believe that abdominal pain is a constant symptom in such cases.

That the abdominal pain was not caused by co-existing disease is rendered almost certain by its presence in the case of stab-wound, in which the heart and other organs were free from disease.

Dr. Naismith considers the abdominal pain to be a reflex sensation, excited by the pressure and irritation of the hæmorrhage. In pericardial effusion there is no pain, because the pouring out of the liquid is slow, and perhaps because the sensitiveness of the surfaces upon which it is poured is diminished by disease; whereas in hæmorrhage the outpouring is comparatively rapid and the pericardial surfaces are normally sensitive. The irritation, passing up the vagus to the centres in the medulla, is reflected down the vagus to the solar and mesenteric plexuses; or, perhaps, spreads in the medulla to adjacent cells connected with the great splanchnic, and so reaches the solar plexus.

RECENT STUDIES IN LEPROSY.

Neither in England nor in America has much been done toward the scientific study of leprosy. In Germany and France, on the contrary, many valuable studies have been made by trained observers and in the leprosy centres of various parts of the world, in Norway, in the Levant, in Palestine, in Africa, China, and the British East and West Indian possessions, medical men placed in favorable positions for study are actively engaged in efforts to ameliorate the conditions of sufferers, and to find palliatives or a cure for the disease if possible.

The papers published by these observers, and their reports made to governments, or to medical societies, are full of interest, and we regret that we can do no more than summarize their results. The literature of leprosy, it must be said, is enormous, and seems to be increasing rapidly.

A recent article by Professor Boinet, "On Leprosy in Hanoi" (Tonquin), in the *Revue de Médecine*, is a particularly interesting one.

As regards the immediate cause of leprosy, the *bacillus leprœ*, but little new has been discovered. The life-history of this organism remains, as yet, a mystery. This much is known, that it in all probability resists the action of putrefactive material, since it is said to have been found in the earth about the graves of lepers. Although the identity of the bacillus thus found is not beyond dispute, yet the fact of several cases of leprosy having been reported as occurring in those handling or exhuming dead lepers is in favor of the existence of the germ, perhaps in some form as yet unknown in the putrefying cadavers of lepers.

That the bacillus was directly conveyed in these cases seems unlikely, because cases of direct contagion, or inoculation in the ordinary sense of the word, have been only rarely reported, and have never gone entirely undisputed. The greater number of cases of supposed contagion have occurred under circumstances which involved exposure to all other influences, namely, climate, surroundings, and food, which have always been known to favor the occurrence of the disease. But a single case occurs to us in which the fact of direct contagion appears almost indisputable. It is Dr. Hawtrey Benson's case of an Irishman who had never left his native land, and who contracted leprosy after having worn the clothes of his leper brother who had come home from India to die. Very numerous attempts have been made to inoculate leprosy upon animals and also upon men. All but one, we believe, proved futile. The one successful case, that of Keaner, the Sandwich Islander, inoculated by Arning, is not regarded as conclusive by that careful observer, since the man

came of a leprous family himself and was brought up among lepers.

On the other hand, the enormous weight of evidence against direct contagion which has accumulated within the last few years would, before the discovery of the leprosy bacillus, have been regarded as perfectly conclusive against the theory of contagion.

Zambaço, a well-known physician of Constantinople, in a pamphlet published a few years ago, gave a large number of examples tending to show the non-transmissibility of leprosy by direct contagion. In some instances great efforts have been made to convey or to receive the disease. Zambaço reports the case of a handsome young woman of good family, who fell in love with a leper and married him. She lived with him for eight years. Partly through jealousy on his part, and partly through devotion on hers, they made every effort to share the leprosy. The leprous husband caused her to kiss his ulcerated tongue repeatedly and numerous attempts at inoculation were made. Nevertheless, while the husband died of leprosy the widow still survives in good health after some years.

With facts like these confronting them, investigators have been led to the conclusion that leprosy is conveyed in some other manner than by direct contact or inoculation of the bacillus.

The theory of an intermediate host has been put forward with the corollary of a transition form of the parasite. We believe there is no analogy among the vegetable parasites to guide us in this matter, such as we have among the animal parasites, but this view is just now exciting considerable attention. In order to ascertain what facts could be adduced, extensive examinations of food, air, soil, etc., in leprosy districts have been undertaken. As regards fish, which has been always more or less incriminated, this article of food in the salted state has, indeed, been found the habitat of numerous varieties of bacteria, and when putrid doubtless contains many more. But no organisms have, as yet, been found in this article of diet which can be connected with the leprosy bacillus.

A curious relationship between leprosy and tuberculosis has been suggested of late, and the resemblance between the two forms of bacillus, together with the fact that the diseases are often concurrent, lends a certain interest to these views, which will certainly be examined into by those having the opportunity of investigation.

Preventive inoculation, which has been talked of for some time, must receive a new impulse from the results of Koch's discovery. Meanwhile, cases of cure seem to be gradually increasing in number, although no new remedies have been discovered.

Looking at the subject from a general standpoint we may hopefully assert that real progress is being made in the study of leprosy, and that there is good ground to hope for the diminution and even the ultimate extinction of the disease in most parts of the world.

REVIEWS.

A HANDBOOK OF THE DISEASES OF THE EYE AND THEIR TREATMENT. By HENRY R. SWANZY, A.M., M.B., F.R.C.S.I. Third edition, with illustrations. Philadelphia: P. Blakiston, Son & Co., 1890.

The third edition of Mr. Swanzy's excellent treatise shows evidence of having been carefully revised and rearranged. The chapters on diseases of the iris, ciliary body, choroid, and sympathetic ophthalmitis have been incorporated into one chapter under the general heading of "Diseases of the Uveal Tract." This, as the author suggests, is more consonant with their nosology, and will lead the student to a much more thorough and rational grasp of the subject. Other changes have been made, especially in the chapter upon the localization of cerebral disease from a study of the ocular symptoms, which has been enlarged and much improved. The addition of a colored diagram, showing the course of the optic fibres, with the centres for the three visual perceptions of light, form, and color and their relations to the field of vision, is a very commendable feature. In explaining Wernicke's symptom, the hemianopic pupillary inaction of hemianopsia, the author does not name the symptom by any of the terms commonly used. Similar omissions to designate properly symptoms by their well-known names result in needless trouble or mystification of the student. But there are few defects to be pointed out, and, viewing the work as a whole, it may be said that Mr. Swanzy has succeeded in producing the most intellectually conceived and thoroughly executed *résumè* of the science within the limits he has assigned himself. As a "students' handbook," small in size and of moderate price, it can hardly be equalled.

CORRESPONDENCE.

KANSAS CITY.

KANSAS CITY has received two invoices of Koch's lymph—one of five ounces and another of two and a half ounces. It is unfortunate that the recipient of one package is making use of it in an irregular manner and in direct violation of his promise to Professor Koch to use it only in hospitals. Aside from this he has thrown discredit upon the lymph by making a very poor selection upon which to begin the treatment, the patient being almost *in extremis*, and dying in a week after the first injection. The death is not attributable to the

treatment, for the latter was stopped after the third injection because of the absence of any reaction and the very alarming condition of the patient. The autopsy showed a general miliary tuberculosis in addition to a large cavity in one of the lungs. So, while the lymph had nothing whatever to do with the patient's demise, the notoriety given it by the daily press of the city has made patients previously anxious to undergo the treatment very cautious and reluctant.

Dr. E. Von Quast, the recipient of the other invoice, has three patients under treatment, and reports that they seem to be improving.

One of the cases of early phthisis had a reaction temperature of 104° F. from 0.001 of the lymph. Another case, one of tuberculosis of the pharynx, does not experience the general reaction, but the local reaction is very marked, and the case is improving. The cases have been under observation but a week, so, of course, it is too early to speak definitely; but those who are watching them have "great expectations," especially in the case of the man who has tubercular disease of the pharynx.

The tidal wave of knowledge is gradually sweeping westward, and the faculties of the two principal schools here are aroused to the necessity of lengthening their courses; one of them has taken steps already in that direction, and the other will soon follow.

Several meetings have been held recently with a view to establishing a post-graduate school here. Certainly, Kansas City needs a post-graduate school, for the majority of the graduates of our local schools choose this city or the surrounding country as localities in which to practise their profession. The plan does not seem practicable to many, on account of the scarcity of clinical material, and the fact that a post-graduate school without an abundance of clinical material would be a farce.

The very mild epidemic of scarlet fever which prevailed during the past few months is subsiding, and the general health of Kansas City is very good.

The meetings of the Academy of Medicine are growing in interest, and the earnest individual effort which is being put forth by the members is resulting in much better papers and discussions.

METHYL-BLUE IN DIPHTHERIA.

To the Editor of THE MEDICAL NEWS,

SIR: Fifty cases of *well-marked* infantile pharyngeal diphtheritis have been successfully treated by me during the last six months by the local application of a mixture of chemically-pure methyl-blue and powdered sugar, two parts of the former to ninety-eight of the latter, controlling the fever with small doses of acetanilid and sustaining the vital forces with extract of beef, egg and milk. The methyl-blue I employ is entirely tasteless and free from all deleterious effects (Lehr & Fink, 128 William St., New York). The manner in which I use it is as follows: The patient's head is held in a horizontal position, the tongue depressed, and from five to ten grains of the powder are freely applied to the pharynx. This is repeated every two hours, or as often as new crops of exudation make their appearance. Sudden elevation of the head must be prevented, the mouth kept closed to prevent spitting, and no drink or food given for ten or fifteen minutes before and after the application.

Retronasal and laryngeal diphtheritis has in none of the fifty cases above referred to made its appearance. Where the nose or larynx was involved at the beginning I could not claim such good results, owing to the already enfeebled condition and the great difficulty of applying the remedy, still I have done better with it than with any other treatment. Washing the retronasal and nasal space with boiled water and applying the powder with the Devilbiss blower have given me the most satisfaction.

I experienced great difficulty in getting the right blue; it is on that account that I mentioned Messrs. Lehr & Fink, who are agents for this article; at the same time, I believe it to be the same as methylene-blue made by Merck (see Merck's Bulletin, January, 1891).

H. BEYER, M.D.

STAPLETON, STATEN ISLAND, N. Y.

A STRANGE CASE OF POISONING.

To the Editor of THE MEDICAL NEWS,

SIR: I was called in haste on the night of December 29, 1890, to see Mrs. P., a married woman, and her child, aged about seven years. On arriving at the house I found them suffering from some strange form of poisoning. On inquiring as to whether any poisonous substance had been taken, I was told that the mother, thinking she was suffering from amenorrhœa, had prepared a decoction from what she supposed to be the root of wild ginger, or Ascarum canadensis, and had taken a considerable quantity of the liquid. The child had also taken some of it with the hope that it would relieve a "bad cold." The symptom which the mother presented was intense pain in the mouth, throat, stomach, and bowels, which was continuous and burning in character. The face, hands, and the lower third of the forearm had the sensation of a thousand small sharp needles piercing the flesh in every direction, and there was also a great deal of burning pain about the wrists. The strangest symptom of all, however, was the eruption which was present. The skin of the face and all the subcutaneous tissues were much swollen, so that one eye was entirely closed and the other eye nearly so. The eruption resembled erysipelas, for the skin was red, thickly covered with pimples and vesicles, while scattered among these were several blisters of considerable size. The eruption was also present about each knee covering a space as big as a hand, being chiefly confined to the popliteal region. In other portions of the body small pimples dotted the skin, and a few vesicles could be found here and there. I forgot to mention that the hands and fingers were much swollen, sufficiently so to make the fingers stand wide apart.

The constitutional symptoms consisted in frequent rigors, accompanied by a fever of about 101°; the pulse was 122 and weak. There was a good deal of nausea and some vomiting. During the remainder of the attack there were considerable swelling, pain, and heat about the anus, and these symptoms were still more marked at the vulva; the labia majora, the nymphæ, and the vagina were greatly swollen, while the burning sensation caused a constant desire to urinate, although micturition was very difficult and painful.

The little girl's symptoms were identical with those of her mother except in degree, all of them being of a milder type, as she had not partaken so freely of the decoction. Another child, who had taken a very small quantity of the liquid, had the same eruption over its body.

The patients made a good recovery, although convalescence extended over three weeks.

I am altogether ignorant of the effects of wild ginger, except the account given in our different dispensatories, and if any of the readers of THE MEDICAL NEWS can give me any information in regard to the use of wild ginger I shall be glad to hear from them. Is wild ginger poisonous? and if so, would it be likely to produce such characteristic symptoms? The husband of the woman gave me some of the roots, which had been collected last fall. They were from two to four inches long, varied somewhat in size, but averaged about the diameter of rye-straws. They were crooked and knotty, very brittle, and gave a pleasant, aromatic taste when chewed, which closely resembled that of cardamom.

JAMES MITCHELL, M.D.

MADISON, BOONE CO., WEST VIRGINIA.

FOREIGN BODIES IN THE ŒSOPHAGUS AND GASTRO-INTESTINAL TRACT.

To the Editor of THE MEDICAL NEWS,

SIR: The potato treatment, which has been so largely employed for the removal of foreign bodies in the gastro-intestinal tract, can well be substituted, in my experience, by the employment of pieces of orange of sufficient size to cause so much dilatation of the œsophagus when the orange is swallowed as to permit the foreign body to fall into the stomach, or, if the foreign body has already reached the stomach or intestines, to entangle it in the meshes of the pulp and ultimately to cause its expulsion from the bowel. In a case which came under my care in which a carpet-tack had been swallowed and lodged in the œsophagus a large bolus of orange stopped at a point about half way to the stomach and remained there. The tack had evidently fallen point downward, and had caught in a fold of the mucous membrane, the head of the tack acting as a ledge against which the fruit rested, so that it was impossible to dislodge the foreign body. I gave an emetic, with the result of causing the tack to fall into the stomach during the efforts at vomiting. Physicians will be surprised to find how slowly orange-pulp in mass is digested, as I have frequently seen sections of orange which have been swallowed appear in the fæces, three days after ingestion, almost unaltered. THOMAS HUBBARD, M.D.

TOLEDO, OHIO.

TETANUS.

To the Editor of THE MEDICAL NEWS,

SIR: Having just read an article in THE MEDICAL NEWS of February 7, 1891, upon "A Case of Traumatic Tetanus," it may interest your readers to hear of a case of a similar character which came under my care. During the month of July, 1890, I was called to treat a severe case of idiopathic tetanus occurring in the person of a Scotchman, aged twenty-four years. I administered 20 grains of chloral with 30 grains of bromide of potassium every two hours, keeping the patient constantly asleep with the medicine, only arousing him for the purpose of administering nourishment. Under this treatment the patient made a good recovery.

M. W. SCOTT, M.D.

EMERADO, NORTH DAKOTA.

NEWS ITEMS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 24 TO MARCH 2, 1891.

The following-named officers, having been found by army retiring boards incapacitated for active service, on account of disability incident to the service, are, by direction of the President, retired from active service from this date, under the provisions of section 1251, Revised Statutes: WILLIAM S. TREMAINE, *Major and Surgeon*, LEONARD S. LORING, *Major and Surgeon*.—Par. 19, *S. O. 45, A. G. O., Washington, D C.*, February 27, 1891.

By direction of the Secretary of War, HENRY M. CONN, *Major and Surgeon*, will report in person to the commanding officer, Fort Adams, Rhode Island, for temporary duty at that post, until the arrival of a successor to Samuel M. Horton, Major and Surgeon, when he will return to his proper station.—Par. 8, *S. O. 45, A. G. O., Washington, D. C.*, February 27, 1891.

FREDERICK W. ELDREY, *Captain and Assistant Surgeon*, having been examined by a board of officers, and found physically disqualified for the duties of a surgeon, with the rank of major, by reason of disability incident to the service, is, by direction of the President, retired from active service with the rank of major, under the provisions of the Act of Congress approved October 1, 1870, to date from February 24, 1891, the date from which he would have been promoted, by reason of seniority, if found qualified.—Par. 1, *S. O. 45, A. G. O., Washington, D. C.*, February 27, 1891.

The following-named officers, having been found by army retiring boards incapacitated for active service, on account of disability incident to the service, are, by direction of the President, retired under the provisions of section 1251, Revised Statutes: J. VICTOR DE HANNE, *Captain and Assistant Surgeon*, WILLIAM R. STEINMETZ, *Captain and Assistant Surgeon*.—Par. 18, *S. O. 44, A. G. O., Washington, D. C.*, February 26, 1891.

By direction of the Secretary of War, WILLIAM O. OWENS, JR., *Captain and Assistant Surgeon*, is relieved from further duty in the Department of the Missouri, and will report in person to the commanding officer, Jefferson Barracks, Missouri, for duty at that station, and by letter to the Superintendent of the Recruiting Service.—Par. 2, *S. O. 44, A. G. O., Washington, D. C.*, February 26, 1891.

The following-named officers, having been found by army retiring boards incapacitated for active service on account of disability incident to the service, are, by direction of the President, retired from active service this date, under the provisions of section 1251, Revised Statutes, JOHN DE B. W. GARDINER, *Captain and Assistant Surgeon;* ROBERT W. SHUFELDT, *Captain and Assistant Surgeon*.—Par. 12, *S. O. 43, A.G. O., Washington, D. C.*, February 25, 1891.

BLENCOME E. FRYER, *Lieutenant-Colonel and Assistant Medical Purveyor*, having been found incapacitated by the army retiring board, on account of disability incident to the service, is, by direction of the President, retired from active service, this date, under the provisions of section 1251, Revised Statutes.—Par. 15, *S. O. 42, A. G. O., Washington, D. C.*, February 24, 1891.

By direction of the Secretary of War, the leave of absence granted ALONZO R. CHAPIN, *Captain and Assistant Surgeon*, in S. O. No. 17, January 31, 1891, Department of Dakota, is extended one month.—*S. O. 41, A. G. O.*, February 20, 1891.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

GASTRO-ENTEROSTOMY WITH RAWHIDE AND SEGMENTED RUBBER PLATES.

BY F. B. ROBINSON, B.S., M.D.,

PROFESSOR OF ANATOMY AND SURGERY IN THE TOLEDO MEDICAL COLLEGE, TOLEDO, OHIO.

GASTRO-ENTEROSTOMY is an operation to establish a permanent fistula between the stomach and some part of the intestine. The term is a generic one, and under it may be included gastro-duodenostomy, gastro-jejunostomy, gastro-ileostomy, and gastro-colostomy. It signifies a communication of the cavity of the stomach with the lumen of the intestine through their respective contiguous walls, and is simply gastro-intestinal anastomosis.

The object of the operation is to overcome an obstruction, malignant or non-malignant, in the pylorus or in any part of the intestinal canal that can be excluded by the anastomosis. The advantage of gastro-enterostomy is that by means of it no structure need be removed. None of the functions of the digestive tract are destroyed in the operation, since physiologically the gut is only partially excluded. All the glands, nerves, bloodvessels, and lymphatics in the excluded intestine can perform their duty in the natural way, as the secretions of the mucous membrane can escape in both directions, and still aid in digestion. In short, gastro-enterostomy permits the contents of the stomach to pass into a new channel with the least possible disturbance. As a surgical procedure this operation possesses all known advantages—no important bloodvessel is cut, no vital function is destroyed, and no great nerve-plexus is injured, and it has the prime essential of all intestinal operations—it is short in duration. It may be considered a successful rival and substitute for pylorectomy. As the operation is a much less serious procedure than pylorectomy, it will have a greater field of usefulness, and will be oftener employed. In gastric cancer it has the great advantage of prolonging life with little or no suffering. It does this by putting the diseased parts in a state of rest. The disadvantage of gastro-enterostomy is also obvious—that is, it does not remove the disease. Whether the tumor be a slow-growing, non-malignant neoplasm, or the erratic proliferation of the malignant cell, gastro-enterostomy does not in the least interfere with the growth; hence, whatever the disease may be, it continues after the operation as before, except that it is not irritated by the passage of the contents of the stomach. It would be a disadvantage to a patient to do this operation for a non-malignant stricture of the pylorus if the stricture could be successfully dilated, for the natural channel is better than an artificial one. An artificial channel does not have a perfect sphincter, is liable to contractions and dilatations, and hence does not regulate the passage of the contents of the stomach.

When gastro-enterostomy has been done, it is difficult to obliterate the artificial fistula. When the dangerous pylorectomy is done it removes, as far as possible, the offending growth, and thus may prolong life; but the close proximity to vital organs, the difficulty of its execution, the prolonged exposure of the abdominal viscera, and the manipulations of great nerve-plexuses, all induce profound shock which endangers life. I saw the skilled surgeon, Professor Billroth, tie the portal vein by mistake while doing a pylorectomy, and thus cause the death of his patient. It may be stated in general that gastro-enterostomy has not fully satisfied the expectations of the profession, but that the surgeon who pays particular attention to the operation will not be very much disappointed. Careful observation clearly shows that the operation has not been done on very favorable subjects, and that the disease killed the patients while the operation benefited them. After the operation the patient suffers less, is more useful to himself and less of a burden to his fellows until his death, which is inevitable. Some patients are now alive several years after the operation.

So far as I have been able to ascertain, the operation of gastro-enterostomy has been performed upon man about 140 times, although some of these may be duplicate cases.

The operation was first performed in Vienna by Dr. Wölfler in 1881. He began the operation of pylorectomy, but being unable to complete it on account of the conditions, did a gastro-enterostomy to obviate the trouble. A hole was cut into the stomach and one into the gut, and the margins of the wound were united by the Czerny-Lembert stitch. The patient lived four months. Since that time Billroth, Lauenstein, Senn, Borker, Rydygier, Page, Hahn, Czerny, Luecke, Küster, Winslow, Stamm, Posteniski, Ransohoff, Monastryski, Rocowitz, and others have performed the operation. The most numerous and favorable reports of cases of gastro-enterostomy come from Professor

Luecke, of Strasburg, who with eight operations had seven recoveries.

The last report of Professor Billroth's that I have seen contained eight cases with three recoveries and five deaths. Professor Czerny reported in 1870 that he had done eleven gastro-enterostomies in his clinic with the following results: three died of septicæmia, four died of progressive marasmus or pneumonia in from two to four weeks after the operation, and four were benefited by the operation. At the same time he reported twelve cases of pylorectomy, of which eight recovered and four died. The medical world has long looked upon Professors Billroth and Czerny as the great advocates of pylorectomy, and hence it would be natural to expect equally authoritative and reliable results from this closely-related operation, gastro-enterostomy. Professor Czerny assisted Professor Billroth for several years in the clinic at Vienna, so that the work of these two men is similar. I know from visits to Professor Czerny's clinic in 1883 and Professor Billroth's in 1887, that their work represents the greatest skill, yet their results in these operations are not very flattering. I am convinced that this is chiefly due to late operations on unfavorable cases. It is reported, though I cannot show statistics, that Professor Senn's results have been more favorable. This I think is due to the fact that Professor Senn operates earlier in the course of the disease than is done in the clinics mentioned. Dr. Senn's wide experience in intestinal operations gives him skill and rapid execution—prime factors in gastro-enterostomy. However, the operation must be judged by the kind of cases upon which it is employed, and not merely by death-statistics. The results of gastro-enterostomy are on trial in every country. The final effects on life must be determined by the observation of many cases through a number of years of carefully-recorded work. Brilliant single cases, by good specialists, should not blind us to the generally-observed effects. Extended clinical research is the only mode of arriving at a conclusion upon the subject.

Two results of the operation are to be expected: one is the relief of suffering; the other, the ultimate cure of the obstruction by directing a part or all of the contents of the stomach into an artificial channel. In general it accomplishes these objects well.

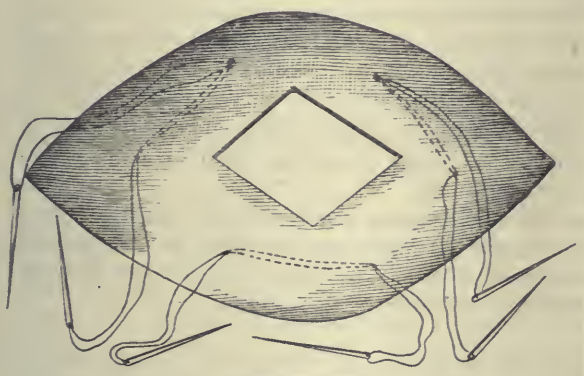
By the old method which Dr. Wölfler employed, gastro-enterostomy was, in my opinion, an unsafe operation. Its dangers lay in the length of time required to perform it and also in the yielding of the sutures; moreover, insufficient rest was given during repair of the wounds, due to non-fixation of the parts. The fistula is not held patent by the old method, while the plates now in use keep the fistula open, thus insuring a lumen large enough for free communication between the stomach and intestine. Experiments taught me some valuable lessons in this work, and by the liberal use of dogs I soon learned to avoid a number of errors. The experiments convinced me that the anastomoses should be made at the most dependent portion of the stomach in order that the food may escape from the stomach with greatest ease. If the anastomosis is made between the gut and the highest part of the stomach, or along the lesser curvature, or even midway up the organ, the animal suffers more or less until all food is expelled from the stomach. By anastomosing the lowest portion of the stomach to the bowel, the artificial fistula is kept sufficiently patulous to prevent obstruction.

The fistula is kept open mainly by the passage of food, flatus, and secretions, and when plates are used they aid in keeping it patent. The operation can be done with the ring and plates in thirty minutes, making it a safe and reliable surgical procedure. When we consider that thirty-five per cent. of *all* cancers attack the stomach, and that of gastric cancers sixty per cent. begin in the pylorus, the supreme importance of the operation is apparent. It seems reasonable that gastro-enterostomy should be substituted for pylorectomy in cancer of the pylorus, for autopsies demonstrate that one-fourth of pyloric carcinomas show secondary deposits in the liver. In such cases pylorectomy is almost useless, while the safer and more easily performed gastro-enterostomy will relieve indescribable suffering until the inevitable end. Even in non-malignant neoplasm, and in stenosis and occlusion of the pylorus, gastro-enterostomy has all the advantages of pylorectomy, besides producing less shock and violence to the system.

It required three years of experimentation to discover the proper material for the plates. In 1889 I began to use cartilage from the scapula of a heifer. At that time I had never heard or read of cartilage plates being employed for this purpose. I abandoned the cartilage plates in a short time, however, as they were absorbed too quickly when thin, and were too clumsy when thick. Some dogs died because of the too rapid absorption of the plates. Various forms of leather were then tried, as the reports of the experiments will show. Finally, I adopted rawhide, and the success of this material in gastro-enterostomy, as well as in many other operations, demonstrates that it is a proper material for securing an anastomosis in the alimentary canal. It is absorbed slowly, and causes coaptation of the large serous surface, producing complete fixation and rest of the parts—essentials for prompt and efficient healing. The rawhide plate is made by shaving the hair from the "green" hide of an ox, and cut-

ting it in strips an inch wide and two and one-half inches long. A diamond-shaped hole one-half by three-fourth inches is then made in the centre. From four to six sutures armed with needles are attached to the plate, and it is ready for use. I used linen thread and ordinary round sewing needles. The thread should be kept in carbolized water or alcohol. The plates can be used either dry or green. Any degree

FIG. 1.



Rawhide plate.

of thickness and hardness may be secured in drying the green hide. The size and rapidity of absorption of these plates can be adapted to the character and quality of the intestinal tract. I secured better results from the use of six than from four sutures. The death of a few dogs induces me to say that in intestinal anastomosis it is not wise to penetrate the incised gut-wall too far from its margin with the needle, as a fæcal fistula is apt to be produced.

Practical examples are always superior to theoretical precept, and so in this paper I will present practical work to demonstrate the operation, technique, material used, and the clinical and pathological conditions and results. The experiments consisted of ten gastro-enterostomies upon dogs with nine recoveries. The wounds were not dressed and the dogs lived together in a cellar.

EXPERIMENT No. 24.—Dog, female, weight twelve pounds. Animal chloroformed, belly shaved, and a loop of small intestine was drawn out through a three-inch median incision in the abdominal wall. An incision one inch in length was made in the convex border of the intestine, and a perforated sole-leather plate (one, by two and one-half inches) was inserted into the lumen of the bowel. The plate had four sutures attached to it, the lateral ones being armed with needles. The needles were passed from the inside of the gut outward about one-third of an inch from the margin of the wound, penetrating the thickness of the bowel wall. The index and the middle fingers were then introduced into the abdomen and a fold of the stomach drawn out, when another plate was introduced in a similar manner into the stomach. The stomach-plate and the incision were larger, and the needles penetrated the wall further from the margin of the stomach than in the previous operation. The serous surface over the plates was then scarified and the plates brought together, the corresponding sutures were tied, first the lowest lateral, then the two end ones, and finally the upper lateral, which brought together accurately the two incised wounds of the stomach and bowel. Just before tying the plates together the serous surfaces between them were sutured by a continuous Lembert stitch. A graft of unsevered omentum was applied closely around the anastomosis and sutured in position. The abdomen was closed by stitches one-third of an inch apart, including skin, muscles, fascia, and peritoneum. The dog made an uninterrupted recovery.

Seventeen days afterward the animal was killed by chloroform and the autopsy revealed the peritoneal cavity perfectly healthy, except a little cicatricial tissue immediately around the anastomosis due to local peritonitis. The graft was firmly adherent to the parts, enclosing the anastomosis in a strong sheath secure against perforation. The union between the surface of the anastomosed parts and the graft was complete, the results of proliferation of connective-tissue cells, bloodvessels, lymphatics, and nerves. Separation of the graft and serous surface was impossible, as it was completely adherent. The anastomosis was made five feet from the pylorus. The plates were in the same condition as when put in, with the exception of a slight softening, and the one in the stomach had commenced to dissolve. They had caused no ulceration by pressure. In seventeen days the fistula between the stomach and bowel had healed and a sphincter-like opening existed which freely admitted the thumb. There was considerable new tissue around its margin. The plates, linen, and sutures were still in position. Upon injecting water into the stomach nearly all of it passed through the artificial fistula. A bunch of straw had collected on the proximal side of the plates, but allowed the passage of food. Almost no food passed through the isolated bowel. It did not appear so vascular and was contracted. My observation is that the excluded membrane at first reacts and becomes congested and red, and later becomes pale. Of course the redness is more apparent, because the membrane is not stained by bile passing over it. The dog lost somewhat in weight.

Remarks.—The stomach-plate would have been absorbed and the intestinal-plate would have passed per rectum had the dog been allowed to live. Sole-leather, however, is not a good material for intestinal anastomosis. Such a dog fed on soft food will have no obstruction for months, at least. But if allowed to roam about, enteroliths will form on the proximal side and cause dangerous obstruction. The straw, bones, and shreds of food become entwined around the plates and will sometimes enlarge the artificial fistula to almost three times its original size. Practical experience teaches me that the artificial opening will contract to one-third or three-

fourths of its original size, and hence the incision must be made large enough to allow contraction. Linen thread does just as well as silk for this purpose.

EXPERIMENT No. 26—Operation was performed as in Experiment 24, and the dog was killed eighteen days after the operation. The abdominal viscera were healthy. The anastomosis was completely healed and the contents of the stomach had been passing through the new channel. The fistula easily admitted the thumb. It had contracted to one-third of its original size. The plates were still in position. Water injected into the stomach escaped almost entirely through the new channel. The excluded bowel was pale, contracted, and slightly stained with bile. The anastomosis was made three feet below the pylorus. The omental graft had formed firm adhesions. Adhesions had formed between the stomach and the ascending colon at a point just above the cæcum.

Remarks.—Sole-leather plates must be abandoned on account of their insolubility. The omental graft should be severed. All raw places in the abdominal cavity should be covered by peritoneal grafts, as bands of adhesions are apt to arise, which may catch and strangulate the intestines. Both operations demonstrate that fæcal accumulation will not occur in the excluded bowel, and that the opposition once raised in the French Academy of Medicine against gastro-enterostomy on account of this supposed accident is groundless. The fæces will take the direction of least resistance. The operation was completed in about thirty minutes, and the shock was not great. It seems that in three weeks the fistula had developed a kind of sphincter, due to the periodical dilatation and contraction caused by the irregular passage of the contents of the stomach and flatus. Pressure of the rings on the mucous membrane had caused no ulceration.

EXPERIMENT No. 28.—Dog, male, weight twenty pounds. This operation was conducted in the same manner as were the previous cases, with the exception that rawhide plates were used instead of the sole-leather ones. The dog made an uninterrupted recovery, and was killed on the eighteenth day after the operation. The abdominal organs were healthy. The omental graft had formed strong adhesions, the anastomosis was well established, and water injected into the stomach passed equally well through the new and old channel. The artificial fistula had contracted to about one-half of its original size, being sufficiently large to admit the index finger. The plates were entirely removed; two threads yet remained. The fistula felt and looked like a natural sphincter. In approaching the stomach the great omentum was torn through instead of being pushed to the left. About seven feet of small intestine had slipped through this aperture. This teaches us to avoid making such openings, or in case they are made, to suture them. They would, no doubt, strangulate the intestines if they remained open.

Remarks.—I do not know that rawhide has ever been used in anastomosis in man, but I have demonstrated by many experiments that it is an excellent material for this purpose. The plates never fail to be absorbed in the stomach or upper part of the intestine and if free from tannin they will be absorbed at any point in the alimentary canal.

By mistake I excluded four feet of small intestine in Experiment 28, but the excluded bowel was free from fæcal accumulation and had become atrophied. The advice of Luecke and Lauenstein, to seize the first loop of bowel which appears at the abdominal opening, should be discarded. It is not justifiable, because the loop might be in the lower end of the ileum—a mistake which Lauenstein made, and on account of which his patient died in a few weeks from marasmus.

The duodenum is reached by pushing the omentum to the left, and then searching for the pylorus or the end of the pancreas, which serve as landmarks for this part of the intestine.

EXPERIMENT No. 34.—Dog, male, weight twenty pounds. Operation performed in the same manner as before, rawhide plates being again used. Dog made a good recovery, and was killed in eleven days. The abdominal organs were healthy. I had intended to anastomose the transverse colon with the stomach, but the autopsy showed that the rectum was united to the stomach, hence, the alimentary canal consisted of the stomach and part of the rectum. The stomach had been dilated to one-fifth larger than normal, by the constant dragging upon it. When water was poured into the stomach it all passed through the artificial opening. The fistula felt like a sphincter, and admitted the index-finger. It had contracted to one-half of the original size. Though nearly all of the bowel was excluded, the dog had neither marasmus nor fæcal accumulation. The plates were entirely absorbed.

Remarks.—The mistake of seizing the rectum for the transverse colon should be remembered. Eventration, however, is the only proper method of accurately locating the parts to be anastomosed. The bowel should be passed through the fingers and carefully inspected. This experiment demonstrates that rawhide is a proper material for use in gastro-enterostomy.

EXPERIMENT No. 36.—Dog, female, weight thirty pounds. I had performed a splenectomy seventy-nine days previously to this operation, and had extirpated the cæcum thirty-five days previously to the gastro-enterostomy. Rawhide plates were introduced and secured by six ligatures. The dog recovered from the operation and ate voraciously, but died on the fifteenth day from marasmus. She lost considerable flesh from the first operation, much from the second, and more from the third.

The autopsy showed that each wound was completely healed. The plates were entirely absorbed. The anastomosis was well established and the artificial fistula was contracted to one-half of its original size and had a sphincter-like appearance, admitting the little finger. The stomach was attached to the jejunum two feet from the pylorus. Scarcely a vestige of fat could be seen in the dog. The peritoneal graft that was applied to the anastomosis had thrown out a wall of exudate which completely sealed the wound and held the parts firmly in place. All that remained of the spleen was a contracted cicatrix. Nothing remained in the place of the extirpated cæcum except a few scars.

Experiment No. 39.—Dog, male, weight twenty-five pounds. The material used in this operation was segmented rubber rings armed with six sutures and six needles, the tubes being held together by four strands of green rawhide. The rings were introduced into the bowel and stomach in the same manner as the plates. The animal completely recovered and was killed eight days after the operation. It lost four pounds in this time from marasmus. The abdominal organs healthy; bands and adhesions existed. The rings were gone and the anastomosis was perfect. Water passed equally well through the natural and artificial channel. The omental graft, three by four inches in size, was torn from the part of the omentum which lay over the stomach, but had firmly adhered to the parts. A curious accident, similar to the one mentioned in a previous experiment, occurred after this operation. Eight feet of the small intestine had protruded through the aperture in the great omentum and were tightly held by the constricting band.

Remarks.—This accident teaches us that either the graft should be taken from the edge of the omentum, or that the omental aperture should be resutured.

Experiment No. 50.—Dog, male, weight twenty pounds. Rawhide was used in this operation. The animal made an uninterrupted recovery and was killed in seven days. The omental graft was firmly adherent. The stomach plate had completely disappeared and the intestinal plate was about one-fourth absorbed. These plates were made of rawhide belt-leather, which contained considerable tannin. The anastomosis had completely healed, and the passage of the stomach contents through the new channel was well established. The fistula was contracted to one-third of its original size. Two feet of bowel were excluded. The omentum was found attached to the median abdominal incision.

Experiment No. 52.—Dog, male, weight twenty pounds. The material used for this operation was green rawhide from which the hair had been shaved. The plates were armed with the usual number of sutures. The opening in the intestine was one inch, and that in the stomach one and a half inches in diameter. The serous surfaces over the plates were well scarified, and the plates carefully tied together. An omental graft was applied and held in position by sutures. (The plates should always be put in the convex side of the bowel.) The dog made an uninterrupted recovery. He was killed eight days after the operation. The abdominal organs appeared healthy; the healing of the anastomosis was perfect and the omental graft was firmly adherent. As far as we could ascertain, all of the contents of the stomach had been passing by the new channel. The opening had contracted to one-half of its original size, and was in a firm sphincter-like condition. The anastomosis was made three feet below the pylorus.

Experiment No. 21.—Dog, male, weight thirty-five pounds. The same material was used in this as in the previous experiment. The dog died in fifty hours, from a fæcal fistula at the site of the plate. The stomach-plate was about one-fourth absorbed, and nearly all of the absorption had taken place at the pyloric end. The intestinal plate was softened, but not absorbed. The omental graft had healed well, except at the point of septic infection.

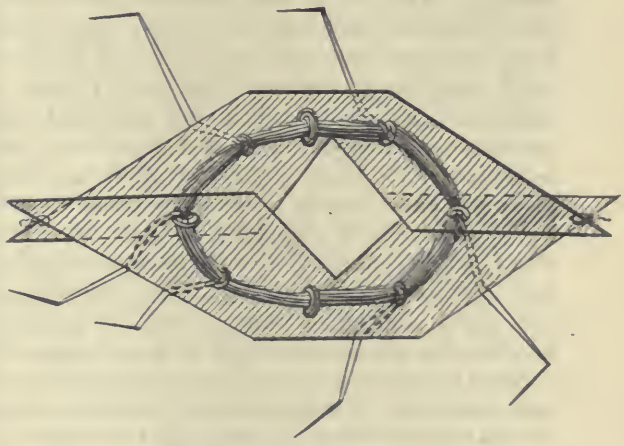
Remarks.—I think the result might have been different had I secured the plate in position with six instead of four sutures.

For the past eight months I have been using other kinds of plates for intestinal anastomosis, hoping that I might discover a still better material than rawhide, though it had proved so far almost a perfect success. I wished to secure something that is cheaper and more easily prepared than rawhide.

After considerable investigation I discovered that segments of thin flat rubber and a ring of rawhide make the best plates that I have yet tried.

I have used rings of sheepskin and catgut instead of the rawhide, but find that one is just as good as the other.

Fig. 2.



Segmented rubber plate.

I have called this new plate the segmented rubber plate. It is made of rubber bands, which should be from two and a half to three inches long, three-quarters of an inch wide, and about one-twelfth of an inch thick. Very thin rubber is best, a piece of an Esmarch bandage being sufficient. The corners of the rubber are clipped off from one side of each seg-

ment, and a triangular piece is cut out of the opposite side of the segments to allow of a channel for the passage of fæces. The rubber segments should then be stitched together at each end with catgut. After making a ring of rawhide, catgut, or sheepskin, it should be stitched to the sides of the rubber plate with two catgut sutures; thus the rubber plate and ring are held together by catgut only. Now apply the six sutures armed with round needles and the plate is ready for use. Dr. Matas, of New Orleans, kindly sent me his solid catgut ring, which he thinks is a good ring to apply to my segmented rubber plate. Its principle is about the same as the ring of rawhide that I used a year ago.

The claim I make for this segmented rubber plate is that it has been successful in my experiments, that it is easily made, and it is absorbed in the proper length of time. It is superior to a ring, as all plates are. It brings into coaptation the largest amount of serous surfaces and holds them closely together.

The plate produces uniform pressure in all directions. There are no uneven surfaces to cause gangrene or sloughing of the gut, which would produce fæcal fistula. The plate produces the most perfect fixation of the parts and allows healing to go on. An essential in these operations is fixation for a certain length of time, as one cannot rely on a definite time for the appearance of plastic exudate. This exudate may be thrown out in a few hours or be delayed more than twenty-four hours. It is exceedingly variable in quantity, and the parts require close approximation so as to prevent leakage. After about one hundred and seventy-five operations extending over nearly three years, I am convinced that a plate should not be absorbed for at least four or five days, and for this reason I abandoned cartilage, which was absorbed too quickly. Some of the dogs died from fæcal fistulæ caused by too rapid absorption of the cartilage plate. I know that in some cases complications have arisen after a coaptation of three days, and thus I put the proper limit of continuous approximation at from four to five days. The rubber plates can easily be made to last a week by properly selecting the material of which they are composed.

Since the introduction of these plates two errors have prevailed. The first error is that rubber which is too heavy is used. I sent a pair of plates by request to a surgeon who wrote that he supposed I had sent him a *model* of the rubber plate, as he considered the rubber bands attached to the plate too light for use.

Heavy rubber will cause gangrene of the gut by its constant elastic pressure. The rubber plate is simply to exert the pressure uniformly in all directions, otherwise Dr. Matas's solid catgut ring, Dr. Brokaw's segmented rubber ring, the author's rawhide ring, or Davis's catgut mats would be just as good. But no ring is as useful as a plate, and no plates, are as cheap and easily made as the rawhide or segmented rubber plate. I have had the greatest success with rubber bands, of which eighteen placed against one another make a plate about an inch thick. Hence the rubber bands composing the plate should be from one-twentieth to one-twelfth of an inch thick.

The other equally erroneous impression is in regard to the size of the holes in the plate through which the needles are passed. Six of these holes are punched in the plate, and should be about one-eighth of an inch in diameter or about the size of a crow quill The purpose of these large holes is to allow the knots and the undissolved part of the ring to become easily disengaged from the plate, as they would aid in producing an obstruction if retained. It must be remembered that if a knot catches in the rubber it will remain in that position until it sloughs through the edge of the artificial fistula, and I have had such threads remain in the edges of the fistula for more than fifty days. Hence, for this reason use thin rubber and make large round holes in the plates. Let me reiterate that the artificial fistula should be made large, for it will generally contract from one-fifth to one-half of its original size; scarify without exception, and always apply an omental graft over the anastomosis.

I have used the segmented rubber plates in many experiments and will report one case of gastro-enterostomy to illustrate the technique.

FIG. 3.

Plates *in situ*. Ligatures ready to tie.

EXPERIMENT NO. 153.—Dog, male, weight twenty pounds. A segmented rubber plate was inserted

into an incision in the stomach one and a half inches in length, and the six needles passed from within outward, penetrating the entire wall of the stomach about one-third of an inch from the margin of the wound. A loop of the small intestine was then withdrawn from the abdominal opening and an incision one inch in length made eighteen inches below the pylorus, into which a segmented plate was inserted. (Fig. 3.)

The two serous surfaces over the plates were scarified and the plates brought into close apposition.

An unsevered omental graft was applied over the seat of operation and fixed in position by a few fine sutures. The recovery of this dog was remarkable, but on the eleventh day after the operation he escaped and we never saw him again. He actually gained flesh during the ten days of his confinement.

It may be said that there is only slight shock succeeding this operation when it is rapidly and skilfully done with plates and the abdominal viscera manipulated as little as possible. In one case the dog nearly died three times during the operation, simply from the dragging on the stomach. No doubt much of the shock in these cases is caused by exposure of the viscera to a lower temperature and the manipulation of the parts.

I wish here to thank Mr. Ame Zetlitz and Dr. C. S. Miller for their able and kind assistance during the past year. Dr. Gillette also aided in some of the experiments.

A CONTRIBUTION TO THE STUDY OF THE COMPLICATIONS OF ACUTE OTITIS MEDIA.[1]

By H. V. WÜRDEMANN, M.D.,
of Milwaukee.

The following case exhibits an unusual number and an alarming severity of those complications which occasionally accompany otitis media, but which are somewhat rare in the course of acute inflammation:

A. M., a painter, aged fifty years, had an attack of epidemic influenza two weeks before he came under my care, which was followed by severe ear symptoms on the left side. The drum-membrane ruptured six days afterward, and great relief from the pain was experienced. The patient had no medical attendance until this time, when his family physician was called, and the case was sent to me for treatment of the ear. The patient's temperature was 101°, and there was great pain over the scalp and shoulder of the left side, with profuse discharge from the meatus. In short, all the usual symptoms of acute suppuration of the ear were present in an exaggerated form. The next day the mastoid area of the left side was red, tender, and somewhat swollen. He complained of visual disturbance, which proved, upon examination, to be left lateral hæmianopsia. The visual field was taken by the fingers at this and at each subsequent examination. Muscæ volitantes also annoyed the patient.

Several attacks of epistaxis of alarming severity occurred during the night. The fever was at times interrupted by chills, and excruciating headache helped to make the patient's condition most deplorable. Phlebitis of the brain sinuses was suspected, and the symptoms pointed to inflammation of the cavernus sinus.[1]

In the course of a few days, under the use of antiphlogistic treatment, these alarming symptoms disappeared, although the pain was at times so intense as to require morphine for its relief. The pain was limited to the left side of the head and extended over the entire distribution of the fifth nerve. All the teeth of the upper jaw of the left side ached.

One week later an inflammation of the external auditory meatus set in, which required the use of leeches and incisions for its relief. In the beginning of the third week a sequestrum of bone seven mm. in length and three mm. in width at its widest part came away in the discharge. The locality from which it came could not be recognized, either from examination of the specimen or from inspection of the tympanum. The discharge was very slight and the perforation in the drum-membrane appeared to be closing. The patient had been steadily growing more deaf upon this side, and in the beginning of the fourth week he complained greatly of increased tinnitus and marked dizziness. At this time another sequestrum was removed by forceps, it having been found to be loose. A few days later no pus was observed in the meatus. The patient was not seen again for about a month, when he returned with the meatus full of pus. He stated that the ear had been dry until a day or two before. This discharge ceased in several days under the ordinary antiseptic treatment.

Two months from the date upon which he was first seen he consulted me, complaining of great pain in the head and of excessive dizziness. He was "flighty" in language, but managed to inform me that he had fallen several times on the way to my office, which was but three squares from his residence. He had been absolutely deaf on the left side for some time. I advised him to return at once to his home. On leaving my office he wandered mechanically down town, where he was arrested as "drunk" by an intelligent policemen and sent to the station-house. After a short detention his condition was recognized to be the result of sickness and not of alcohol, and he was turned loose on the street, to make his way home as best he might, as he claimed to know the way. After four hours' exposure he at length reached home, having fallen a number of times on the way. I was called to see him that night, and found him in bed with delirum and high temperature. In consultation with Dr. William Mackie, meningitis was determined to be the cause of these symptoms. The patient fully recovered from this trouble, after a tedious convalescence. Absolute

deafness has continued, no assistance being rendered by artificial aids. The tinnitus aurium has disappeared entirely, but the vertigo at the present writing, nine months from the inception of the disease, is as pronounced as ever. The patient in walking can prevent himself from falling to the left only by a strong effort at each step. There has been no discharge from the ear for six months, and for four months the membrana tympani has been completely restored.

There has been an entire destruction of the auditory apparatus of the left side.

MEDICAL CASES IN THE COURTS.

BY HENRY A. RILEY, ESQ.,
OF NEW YORK.

THE State of Kansas is old enough, it seems, for cases involving the perpetuity of cemeteries to get into the courts. In a recent case it was claimed that the donors of the land had rights which were not extinguished when the cemetery was dedicated, and that, under certain circumstances, they could claim a reversion of the land and the right to the use of it in the meantime. The judgment of the court is interesting, and we quote as follows: "In the case at bar the donors have devoted the whole use of this land for the purpose of continuous burials and as a place for the repose and memory of the dead. In my judgment no conceivable right of private beneficial enjoyment would remain in the donors, as owners of the fee, which would not be inconsistent with the right of sepulture to which they have devoted it. Crops for their gain and sustenance could not be grown upon its surface, nor could dwellings for their shelter and enjoyment be erected within its limits, without interfering with the solemn use, the sanctity and repose, implied in the purpose of the dedication. The sunshine and laughter of inhabited dwellings, as well as the 'toil and endeavor' of business pursuits, are out of place in cemeteries of the dead.

"According to our law governing the subject of ejectment, the plaintiff cannot prevail unless he has the immediate right of possession at the commencement of his action.

"As long as the rights of sepulture parted with in the donation are outstanding in the public the plaintiffs have no right to recover the use of the land for any enjoyment or purpose of their own."

Hon. Henry Hitchcock, President of the American Bar Association, gave, at the meeting held this year, a detailed statement of legislation during the previous twelve months in the different States, which is of much value to any one desiring to observe the drift of lawmaking.

The meeting was held some months ago, but the information will not seem stale even at this late date.

On the subject of the public health Mr. Hitchcock gives the following interesting statement: "The care of public health is a subject of various statutes in twelve States. New Jersey, Washington, and North Dakota created State Boards of Medical Examiners, without a license from whom no person may lawfully practise medicine, and a license may be refused or revoked for unprofessional or immoral conduct, and in North Dakota 'for publicly advertising special ability to treat or to cure diseases, which, in the opinion of said board, it is impossible to cure,' though an appeal to the Governor is permitted.

"Another act of North Dakota, while recognizing the needs of anatomical science, imposes wise and humane restrictions upon its votaries. Kentucky, by an amendatory act, transfers the licensing power from the faculties of legally-chartered medical schools and the State Board of Health, but forbids any travelling empiric to register or practise medicine within the State.

"As indicating the progress of public sentiment, I recall, with some amusement, a conversation ten or fifteen years ago with a legislator in another State, who indignantly refused to support a similar statute on the ground that if a free American citizen chose to consult a quack doctor, it was nobody's affair but his own; but that State has now, for years, required physicians and surgeons, dentists and druggists alike to be registered and licensed by the State Board of Health. A like growth of public sentiment in another direction is indicated, and the old maxim, 'that prevention is better than cure,' is exemplified by a New Jersey statute authorizing the incorporation, by certificate, of associations for promoting the interests of cycling and athletic sports. New Jersey also enlarges the powers of township boards of health, making further provision against danger from epidemics or contagious diseases in public and private schools.

"New Jersey, Virginia, and North Dakota also forbid the practice of dentistry without previous examination, and license from the State Board of Dental Examiners.

"The sale of drugs is regulated, and their adulteration is made a criminal offence by amendatory or original statutes in Georgia, New Hampshire, New Jersey, North Dakota, Rhode Island, Ohio, and South Dakota; in all of which States it is unlawful for any but a registered and licensed pharmacist to sell drugs, and severe penalties are imposed for their adulteration. In Georgia every manufacturer or vendor of drugs must, on demand by any person interested, furnish a sample for analysis to the State Board of Pharmacy, who are required to prosecute in case of adulteration. Ohio declares what shall be the standard of drugs for purity, and what con-

stitutes the adulteration of food. In New Jersey a vendor of adulterated drugs may defend by showing that he procured them in good faith from a resident of the State, with warranty in a form prescribed—the giving of a false warranty being also a misdemeanor."

The microbes, in their devastating course, have entered the State of Texas, and the Supreme Court of that State has been called on to decide whether a manufacturer, who calls his compound "Microbe Killer," can prevent a rival manufacturer from calling his panacea "Microbe Destroyer." The first designation was placed on a yellow label with a black border, while the second was printed on a white label with a red border, and, in addition, had a pleasing representation of a man striking a skeleton with a club. The court, after ample deliberation, decided that it could not interfere, and that there was no violation of the trade-mark laws.

OPEN DIVISION IN STRANGULATED INGUINAL HERNIA.

By BENJAMIN T. SHIMWELL, M.D.,
DEMONSTRATOR OF SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA.

The classical operation for strangulated inguinal hernia has only partly met the requirements. The advance made in surgery, more especially in that of the abdomen, has allowed a greater liberty of action, which seems not to have been properly taken advantage of in the treatment of this condition.

This paper is written to show the advantage gained by the open method of operating—that is, cutting directly through all the tissues of the tumor, including the external ring, internal ring, and, if necessary, the abdominal wall, converting a simple herniotomy into a hernio-laparotomy.

The condition of the protruding gut is modified by its preëxisting condition, the size of the protrusion, the length of time of strangulation, and the position of the constriction. An old incarcerated hernia with a sudden increase of the protrusion and consequent constriction gives an abnormality in relation of structures and their component characters, that has no resemblance to an acute case and causes a difference in the ultimate results of treatment. The size of the protrusion is not so much a factor in causing constitutional symptoms as is supposed. I have seen as violent symptoms in a small protrusion as in one of greater size.

The length of time of constriction also modifies structural capacities, and directly influences the result.

The point of constriction may be either at the external or internal opening, or, what is often overlooked, the true constriction may be the neck of the peritoneal sac, the inguinal rings acting merely as a barrier to the return of the gut and not as a true constrictor.

A careful consideration of these propositions opens a field of thought that must of necessity show the inefficiency of the nicking of the external ring from below.

The extension of the incision cannot be said to complicate matters by increasing the risks. It is settled beyond peradventure, that careful increase of a few inches in the length of an incision, whether in the abdomen or anywhere else, does not increase the risks.

Compare the old method with the certainty of work and view of field, the definite knowledge of conditions of the injured gut, and the lessening of risks which were due to handling of gut by the drawing down preparatory to reduction.

Would an abdominal surgeon operate in a case with marked adhesions through an opening of the same size that he would in a simple uncomplicated oöphorectomy? Working in the dark is prolific of bad results. It is not in the power of any man who operates for strangulated hernia by the old method to tell with certainty the condition of the bowel, and thus it is that many cases end in death by inflammation of, or ulceration and necrosis of the bowel at the point of constriction. The condition of the congested bowel is the point always to be regarded in determining whether it will regain its normal state. To me it seems that not enough importance is laid upon the condition of the tissue at the point of constriction. There is often an amount of injury done that causes the most serious results. There is the question of necrosis, which is one of importance, and then also the loss of nerve vitality by constant constriction, which is often marked. I have seen this persistent at the end of days, the obstruction still remaining.

Paralysis of a portion of the bowel prevents fæcal circulation; the bowel forces its contents to this point, and then is unable to send them further. Gas and fæcal matter will enter a paralyzed portion. Continuous action is a necessity. As a proof of this point, a patient upon whom I had performed hysterectomy died suddenly from tympany produced by obstruction of the bowels due to paralysis. The case was one in which every means were tried to relieve the condition.

The post-mortem examination discovered the point of paralysis in the lower portion of the ileum. The bowel walls were flaccid at this position for about two inches. Above this the whole canal was enormously distended, while below to the anus it was entirely empty. Experiments on dogs have shown the same results.

It is in the ability to appreciate these conditions properly that the open incision has its

strongest advantages. A full inspection of the injured bowel indicates the treatment where special conditions arise, as does the question of resection when gangrene is imminent, or in those cases in which it is apparent that the point of constriction will not regain its tone. The importance of resection in the latter cases has been impressed upon me by the condition of those that I have seen. This loss of tone is apt to be present in old incarcerated hernias, in which narrowing of the canal by pressure has altered the structure of the walls, and in such cases the increased constriction has injured an already impoverished part. Another advantage is the certainty of the complete return of the protruded gut into the abdomen.

The possibility of a radical cure is to be considered. I have one case that I operated on nearly two years ago, which seems to approach a radical cure. This was a case of true hernio-laparotomy. The internal ring was carefully sewn together, the floor of the inguinal canal was curetted and closed by buried sutures which included the external ring, the superficial surfaces continuous with the abdominal wall being brought together with silkworm-gut. The abdominal cavity was cut off at once and coaptation was so perfect that it tolerated the patient's tearing off all his dressings, walking down stairs and sitting on the front steps in the early morning of the fourth day. When I last saw him he was doing active work and was not wearing a truss.

The closing of the canal can be done, if so desired, by retention of the sac in the upper portion of the canal, using any of the methods suggested. In old incarcerated cases the adherent sac can be separated from the surrounding tissues, leaving a good surface for union, while the sac can still be retained at the internal ring, its serous surfaces simply in contact, or by the purse-string method. The open treatment, the value of which is still doubtful, can be tried.

If the abdominal walls have been divided, care must be exercised to bring into apposition the peritoneum and transversalis fascia, also the superficial fascias that make Poupart's ligament. The latter procedure is a necessity for strength, the sutures entering well into the pubic side to hold the divided ligament firmly together. If this is well done, when union has taken place the ligament can be readily defined and its relations are found to be continuous. Drainage of the pelvis is a necessity if exudation is apt to occur.

1253 SOUTH SEVENTEENTH ST.

Treatment of Acute Vomiting of Pregnancy.—The *Journal de Médecine de Paris* recommends five drops of a solution made up of equal parts of iodine and chloroform, to be taken at the time of eating by women suffering from the vomiting of pregnancy.

A CLINICAL STUDY OF ERGOT.

BY JOHN C. HEMMETER, PH.D., M.B., M.D.,
OF BALTIMORE.

(Concluded from page 269.)

FEW facts have been so well established clinically as the decided effect of ergot on hæmoptysis. Sparjani and Cabini have reported cases of pulmonary hæmorrhage that were almost instantaneously checked by this drug;[1] and Bazzani,[2] Jamieson,[3] and Stewart[4] have put on record a number of cases of hæmoptysis of an exaggerated type that ceased at once upon the hypodermic administration of ergot. This treatment has also found strong advocates in those excellent clinicians, Oppolzer[5] and Thompson.[6]

We have taken the opportunity of testing the efficacy of secale in two cases of dysentery that proved rebellious to treatment with astringents, bismuth, opiates, and even to flushing of the large intestine. After the drug was persistently used the hæmorrhage ceased and recovery occurred. These cases presented no special clinical or physiological interest, except that it seemed that when the secale was injected through a long rectal tube, it had a more immediate and lasting effect than when given by the mouth or hypodermically. A strict milk diet was insisted upon during the entire treatment.

Successful results of the treatment of chronic diarrhœa by secale have been reported.[7]

O. Rosenbach has given secale a place in the therapy of aortic insufficiency and so-called idiopathic dilatation of the heart.[8] As a consequence of the increased pressure of the hypertrophied ventricle, and under the influence of the increased quantity of blood which is thrown into the arteries, the latter are dilated and lose their contractility, so that a very important factor in the propulsion of blood is lost. Rosenbach claims to have obtained good results during the period of disturbed compensation by stimulating the aortic walls to greater activity. He has also used ergot in cases of arterio-sclerosis, in which, as he claims, the incapacity of the diseased portions of the arterial system must be compensated for by an increased activity of those portions that remain healthy. The benefit obtained was shown by the effects on the pulse, which became more regular and slower with a diminution of the attacks of dyspnœa and palpitation. The objections to Rosenbach's treatment are that

dilatation of the heart may be the result, and not the cause, of increased peripheral resistance; that ergot in physiological doses increases endocardial pressure, which may have been the cause of the dilatation, and that in toxic doses it is a heart poison, or injures the ganglia. In disturbed compensation we are in many cases forced to conclude that the ganglia are at fault, and that the breaking down is nervous, not muscular.[9] In one case of aortic insufficiency with marked Corrigan's pulse, Dr. Alan P. Smith, of Baltimore, and the writer witnessed marked improvement of the symptoms under ergot, after digitalis had failed. The aggravated symptoms in this case resulted from cerebral congestion; at times the patient was unable to see the window, and at her best complained of constant headache, giddiness, muscæ volitantes, and stabbing pains over the heart and extending down the left arm. The improvement lasted for six months, during which period the secale was repeated but once. At present, eight months after secale was first given, the patient is doing well. In a second case, one of mitral regurgitation, with a tendency to pulmonary engorgement and hæmorrhage, ergot proved a useful drug. There is one form of abnormal pulse which is, without exception, very much improved, if it does not disappear under secale—this is the dicrotic pulse. This pulse is caused by a very low degree of pressure in the arterial system, and a very short systole. In fever the elevated temperature causes a low arterial pressure, the vessels being dilated, the systolic contractions being too short and following each other too rapidly, constituting the conditions for dicrotism. Ergot fulfils all the requirements necessary to counteract these deviations from the normal. It increases arterial pressure, renders the systole slower, gives the vessels increased tonicity, and reduces the temperature.

We hoped to be able to present pulse-tracings and clinical charts from cases of meningitis and catarrhal pneumonia, showing the fall of temperature and reduction in number of the pulse-beats after hypodermic injections of ergotole in a case of meningitis, and also from a case of catarrhal pneumonia, showing slowing of the pulse-rate with increased tonicity and diminution of the number of respirations, but want of space forbids their insertion.

It is possible, by careful and long-continued ophthalmoscopic study of the fundus of the eyes of epileptic patients, to form an accurate conception of the dimensions of the vessels of the retina. The vessels can in fact be measured, if it becomes necessary, by an ophthalmometric attachment to the instrument. For these observations such patients are best adapted who, in addition to epileptic seizures, present a more or less constant congestion and engorgement of one fundus, right or left, during the intervals between the attacks. When patients afflicted with *grand mal* complain of hemicrania during the intervals of rest and health, a careful ophthalmoscopic comparison of the two fundi should be made. If congestion is evident in one or both fundi, ergot should be tried, and should the drug produce its characteristic effect and the constriction of the arterioles and capillaries of the retina be evident after its administration (after 3 fluidrachms of fluid extract or 2 fluidrachms of ergotole have been given), the drug should by all means enter into the treatment of these particular cases. It should be borne in mind that the ophthalmoscopic study of the action of ergot should be made in the intervals between the seizures. We have made these statements on the basis of over two years' study of more than fifty epileptics at the Baltimore Insane Hospital. Among the symptoms that should direct attention to possible cerebral congestion are contracted pupil, hemiopia and diplopia, supraorbital pain and narrowing of the field of vision, and aggravation of the symptoms by the recumbent position and acts involving deep inspiration, as blowing, sneezing, etc. The restriction of the visual field is often present on the side on which the hemicrania is complained of. In the cases of epilepsy that have been specified, combined treatment by bromides and ergot did not, it is true, cure a single case, but it greatly reduced the number of attacks, which is one step in the right direction. The records of epileptic attacks at the Baltimore Insane Hospital during the period referred to, were kept as carefully as possible by day and night nurses. The following is a tabulated statement of seizures occurring from April to September, 1886, inclusive, in four congestive epileptics, two males and two females. Under simple bromide treatment the number of attacks in these six months was 121. In the following six months the bromides were combined with ergot in the treatment of the same patients, and the number of attacks during this period was 31.

[1] Osler: American System of Medicine, vol. iii. p. 629.

In our experience, cases of simple hemicrania, with the ophthalmoscopic appearances and other evidences of cerebral hyperæmia, have been relieved by the use of ergot without any other medication. In a case of migraine associated with a very irritable stomach, ergotole hypodermically gave gratifying results. In brief, whenever uncomplicated cerebral hyperæmia can be definitely discovered, ergot is the drug *par excellence*. In all cases of cerebral or spinal hyperæmia it is important to remember that ergot is a drug for the relief of acute symptoms only, and should not be long continued.

In the course of our studies upon ergot we have had the opportunity to observe its effects on three cases of posterior spinal sclerosis in which the symptoms became worse every time the drug was given and improved as soon as it was discontinued. One of the cases was at Bay View Hospital, the other two were in private practice. In a man aged forty-two years, who could walk fairly well and whose sight was good, who received ergot to relieve his lightning-pains, these pains became intolerable after the third drachm of fluid extract of secale cornutum had been taken. The patient often lost his equilibrium, and fell repeatedly from inability of coördination ; a persistent nausea prevented further ingestion of the medicine, after which the man improved. On the following day we resumed the ergot, and the same symptoms were repeated, the patient even showing evidences of ptosis. Being convinced that the medicine was the cause of the trouble, it was discarded, and the case once more improved. About six months subsequently, the same patient, who had in the meantime consulted a northern specialist, returned with aggravated ataxic symptoms, ptosis, and evidences of mental alienation. He was taking a dark-red medicine, which we found, on writing to the druggist who had compounded it, to contain a half-drachm of fluid extract of ergot to the dose. This medicine was stopped, the man improving decidedly within a week, the ptosis disappearing.

The patient in Bay View Asylum had a typical iridoplegia, an Argyll-Robertson pupil, the belt sensation, and a paretic gait, but his cutaneous sensibility was not impaired, tingling and formication in the feet being the only sensory disturbances.

The patient had not complained of pain. After taking ergot (half-drachm of fluid extract three times daily) for one week he suffered from agonizing lancinating pains and a burning sensation over the sacrum. Movement of the lower extremities was almost impossible, and marked anæsthesia was found all over his legs. Incontinence of urine was present, and he also complained of seeing things double. These symptoms improved as soon as the secale was stopped, and returned with almost equal severity four months later when he was again recommended to take it.

In a third case of locomotor ataxia similar aggravation of symptoms occurred under ergot; the symptoms were not, however, so severe, as the patient had learned to recognize the smell and taste of the fluid extract of ergot, which had formerly been given to him in drops, and refused to take it, asserting that it "always made him worse."

We are forced to the belief, from these observations and those of others that in spinal and cerebral diseases ergot is a dangerous agent to use if decided histological changes have occurred in the brain or cord. Benefit may be expected from it in only certain well-defined congestive epilepsies, in simple hyperæmia of the brain and cord, and in congestive hemicrania.

After carefully studying the literature of this question, we find that cases of locomotor ataxia have already been reported in which the symptoms were directly aggravated by the use of ergot.[1]

From what we have learned concerning the damaging influence of this agent on general metabolism, and from the fact that its action is solely exerted, in a manner which cannot be experimentally established, by producing certain molecular, perhaps chemical, changes in the central nervous organs, we may argue that it should not be employed in acute myelitis, in acute spinal meningitis, in infantile spinal paralysis, or in posterior spinal sclerosis. In the psychoses it should find application only to relieve acute congestive symptoms, and then it sometimes works admirably. We cannot agree with writers who recommend ergot in sclerotic diseases, particularly in tabes. It is well known that this substance itself, when administered in large doses or for a long-continued period, can produce sclerosis of the cord. Spitzka[2] has seen a tabetic patient, advanced in the disease, who had received the drug for three weeks in such quantities that it was estimated that he had received more than some of the patients in whom Tuczek discovered the development of ergotin tabes. The proof of the existence of congestion and engorgement of the vessels at the onset of tabes has not been furnished ; as a rule, the vessels are found sclerosed and narrowed. Spitzka points out that in the natural progress of tabes the lightning-like pains disappear, usually, about the time the anæsthesia becomes greater. The reason for this is supposed to be the destruction of the nerve-tubes whose previous irritation caused the pains. If, as is claimed, ergotin does produce amelioration of the lightning-like pains, it would be a damaging revelation to show that it does so in imitation of the natural process—that is, by increasing the sclerosis.

Ergot in diabetes mellitus.—It is not within the scope of this paper to dwell fully upon the pathology of glycosuria. This subject received much consideration at the last International Medical Congress,[1] where the debate concentrated the wide experience of such authorities as Pavy, Seegen, Dujardin-Beaumetz, de Renzi and Enrico Reale. An excellent summary of our present knowledge of the pathological anatomy of this disease has been furnished by Dr. Robert Saundby.[2] From the point of view of rational therapeutics it would be an important gain to have the various forms of diabetes classified more in accordance with their apparent etiological basis. We might thus distinguish cerebral, spinal, ganglionic, neurotic, salivary, pancreatic, duodenal, hepatic, and hæmatogenous diabetes mellitus. The hepatic form might be eliminated, because it seems probable that the liver is in no case either primarily affected or the primary cause of the disease. Section or paralysis of the vasomotor conducting paths from the centre to the liver is always followed by glycosuria. A number of hepatic nerve-fibres leave the cord high up and enter the sympathetic paths to the liver, and the disease has been observed to follow destruction of the upper cervical ganglion (Pavy), of the lower cervical and of the first thoracic ganglion[3] of the abdominal ganglia (Klebs and Maunk), and also of the splanchnic nerve (Hensen and v. Graefe). As a consequence of destruction or paralysis of these structures there results vasomotor paralysis of the hepatic circulation. The expanded vessels engorge the liver with blood, which flows through the organ at low pressure and very slowly. This disturbance in the hepatic circulation causes an abundance of sugar formation in the liver, as the blood-ferment has ample time under these conditions to metamorphose the glycogen. Normally the vasomotor system of the liver is to be looked upon as exercising an inhibitory influence over the transformation of glycogen into sugar. The first four varieties, cerebral (Claude Bernard's puncture of the floor of the fourth ventricle), spinal, neurotic, and ganglionic all produce mellituria by causing the same changes in the liver; *i. e.*, vasomotor paralysis. It was to combat the hepatic engorgement that ergot was recommended in this form of diabetes. There are, however, other forms over which ergot cannot possibly have any kind of controlling influence. Lepine, of Lyons, has produced very plausible evidence that there is a form of diabetes which is due to a deficiency of the diastatic ferment in the blood. The following are his reasons:

1. The blood of a diabetic dog contains this ferment in much less quantity than the blood of a healthy dog.

2. Diastase injected in the dose of one grain into a diabetic dog diminished glycosuria.

3. Diastase injected in the same dose under the skin of a diabetic man diminished glycosuria.

Such a form of the disease as this might be termed hæmatogenous, as it depends upon some change in the composition of the blood. Ergot could, of course, exert no influence on this morbid change.

At the Tenth International Medical Congress Drs. de Renzi and Enrico Reale presented a joint communication on their experiments on diabetes, from which it appears that, experimentally at least, there are pancreatic, duodenal, and salivary forms of diabetes, as extirpation of the pancreas, duodenum, or salivary glands causes this disease. These observers also come to the conclusion that there exists in the organism a ferment occurring in varying amounts in the different organs, which ferment destroys sugar.

It appears that ergot is of no utility in pancreatic, salivary, duodenal, and hæmatogenous (absence from the blood of diastatic ferment) diabetes. We have records of two cases of well-marked diabetes in which ergot did not at all reduce the amount of sugar in the urine or the total quantity excreted; whereas the same cases improved as soon as the ergot was discontinued, and the patients were put upon opium and tinctura ferri chloridi. In both methods of treatment the patients were kept on a diabetic diet.

Addenda to experimental portion of this paper, published in The Medical News, January 31 and February 7, 1891:

1. In studying the effects of ergot on blood-pressure, the drug, as was stated, was allowed to run into the jugular vein diluted with defibrinated blood. We omitted to state that defibrinated blood injected alone had no influence on blood-pressure.

2. A second series of experiments to obtain tracings of uterine contractions with the manometer failed for reasons already stated.

3. Under the head of causes of reduced temperature under ergot we omitted to refer to a possible effect on the glycogenic functions of the liver, which is one of the metabolic processes that raise the temperature of the blood. There are no experimental methods at our command to investigate this question.

4. In estimating the influence of ergot upon the rate of the blood-current, the amount of blood which flowed from a cut artery was first measured under natural conditions and then after the administration of ergot. The amount under ergot was less than the amount before it was injected. But the blood-pressure falls with the vital powers as an animal bleeds, and

the reduction might be due to this and not to ergot. Upon Professor H. N. Martin's advice we then used the Ludwig Stromuhr. It was found after repeated experiments with the Stromuhr (testing the rate of the blood-current under ergot) that the time required to fill the glass globes was a more correct indication of the effect of ergot in slowing the current than calculating the number of millimetres, which differs in both carotids according to their diameter and according to the size of the globes. These varying periods of time were:

	Normally.	Under ergot.
Dog, No. 3, a,	34 seconds.	58 seconds.
" No. 5, b,	35 "	1 minute.
" No. 6, c,	36 "	1.5 minute.

5. Our thanks are due to Professor H. N. Martin for much kind advice.

THE LIGATURE OF ARTERIES.[1]

BY STEPHEN SMITH, M.D.,
OF NEW YORK.

THE opening years of the present century were notable in the history of surgery for the extraordinary attention given to the ligature of arteries. The fame of Hunter's successful application of a ligature to the femoral artery for popliteal aneurism had led to renewed inquiry as to the nature of the changes which occur at the seat of ligation and as to the applicability of this operation to other arteries. The field of practice which was now opened was new and most inviting, especially to the younger surgeons. The treatment of aneurisms had hitherto proved most unsatisfactory, but now the way to success had apparently been definitely pointed out, and many were ready to test the value of the new method. Far greater interest, however, was manifested in the operations in England than in France, or other Continental countries. American students were then more frequently educated at the British schools, and the enthusiasm which pervaded the profession at these centres was imparted to the Americans. As a consequence, both British and American surgeons have won the greatest honors in this department of surgical practice.

It is the purpose of this paper to notice more especially the contributions of American surgeons to the improvement and development of the ligation of arteries.

The history of the ligation of arteries for the cure of aneurisms may be divided into three periods. The first period came down to 1785; the second extended from 1785 to 1868; and in the third we are living at present. The recognized operation in the first period is called the old method; that of the second period the new method; that of the third, or present period, the antiseptic method.

The old method dates back to the Greek writers. The principle on which it was based was the obliteration of the tumor by freely opening the sac and promoting suppuration. The feature of the operation which excited most interest among surgeons, and led to improvements, was the method of arresting hæmorrhage. At first the open artery was plugged after the sac was incised—pledgets containing caustic being sometimes employed. Subsequently, the open artery was ligated at the bottom of the sac, and then the sac was filled with lint or other materials, and allowed to suppurate. A still further improvement was the ligation of the vessel, externally but close to the tumor, and the subsequent incision of the sac. Again two ligatures were applied, one above and the other below the tumor. But, whatever method was employed to prevent hæmorrhage, the operation terminated by opening the sac. This operation is described by observers of that period as being most disastrous into results. The suffering of the patients was most severe and the mortality was enormous.

In 1710 an operation was performed which was a radical departure from the old method. For the first time, apparently, the aneurismal tumor was not laid open after ligature of the artery. It was the ligation of the brachial artery by Anel. The patient had an aneurism at the bend of the elbow following venesection, and Anel applied the ligature as near to the tumor as possible. In this respect the operation did not differ from that practised at the time. But he did not touch the aneurism, as was the custom, and was gratified to see the tumor gradually diminish and finally disappear. This operation did not, however, attract attention for three-quarters of a century, and the old method continued to be practised until 1785. It is not difficult to discover, however, in the surgical literature of that time a growing discontent with the operation, and courses of inquiry, which must in the minds of the leading thinkers and observers ripen into radical changes in practice. Pott, in England, and Deschamps, in France, discarded the operation, and preferred amputation of the limb in which the aneurism was located. Cases of the spontaneous cure of aneurism were studied in London, and in one instance John Hunter is reported to have been in consultation in such a case.

The first authentic departure from the old method after Anel's operation occurred in June, 1785, when Desault repeated his operation for a popliteal aneurism, and with success. It has been claimed by French authors that this operation inaugurated the new method, but according to Sabatier the ligature was applied at the upper part of the tumor, and the operator had to separate the nerve from the artery. These facts prove conclusively that the operator applied the ligature close to the tumor, as did Anel. These operations were certainly important steps in advance, and demonstrated all of the possibilities of a century of subsequent improvements. They proved conclusively that the ligature of the artery on the proximal side of the tumor might result in obliteration of the aneurism without opening the sac. Anel's remarks upon his case show that he based the operation upon physiological conclusions, and that it was not an accidental or an empirical procedure. He states that, after ligating the artery, he did not touch the sac, "not doubting but that the blood contained in it would be dissipated, being at liberty to pass on toward the extremity; that the sac, being once empty, would not fill again; that the layers of membrane that formed it would not fail to collapse; and that thus the tumor would disappear, all of which happened as I thought." The de-

[1] The Address in Surgery before the New York State Medical Association, Oct. 23, 1890.

fect in this operation was the application of the ligature so near to the aneurism that it was liable to be placed on a diseased portion of the artery, and hence lead to a fatal result from secondary hæmorrhage. Hunter recognized this fact, as the accident had happened several times to him, as appears from Home's account of his operation, and sought to remedy the defect by applying the ligature to the artery at a point sufficiently distant from the aneurism, on the proximal side, to insure healthy tissue.

Home, who reported the case, remarks as follows:

"The common method of operating in cases of popliteal aneurism having in many instances proved unsuccessful, the operation itself has been condemned by some of our most eminent surgeons. If we consider the cases in which it has been performed, and where the patients have died, we shall probably find that in all of them the artery had been diseased at the part enclosed by the ligature, and had either sloughed off, or had been cut through where it was tied, so that the sides of the artery, though brought together, had not remained a sufficient length of time in that situation to unite by the first intention, and the patients lost their lives from the consequent hæmorrhage."

These statements of Home undoubtedly embody the reflections of Hunter upon the causes of the fatal issue of the old method as modified by Anel, and as recently practised successfully by Desault.

It naturally followed that Hunter should propose to ligate the artery at a higher point, and the reasoning which led to his now famous operation is thus given by Home:

"The femoral and popliteal arteries are portions of the same trunk, presenting themselves on different sides of the thigh, and are readily come at in either situation; but where the artery is passing from the one side to the other, it is more buried in the surrounding parts, and cannot be exposed without some difficulty. In performing the operation for the popliteal aneurism, especially when the tumor is large, the ligature is commonly applied on the artery at that part where it emerges from the muscles. This will be too limited a space should it prove diseased for some way higher up; and, if the artery should afterward give way from any of the causes above mentioned, there will not be a sufficient length of vessel remaining to allow of its being again secured in the ham. To follow the artery up through the insertions of the triceps muscle, to get at a portion of it where it is sound, becomes a very disagreeable part of the operation; and to make an incision on the forepart of the thigh to get at and secure the femoral artery, would be breaking new ground—a thing to be avoided, if possible, in all operations."

In December, 1785, six months after Desault performed his operation, Hunter had the opportunity of putting into practice his preconceived views. The point of ligation was "rather below the middle of the thigh," which must have been about the entrance of the artery into Hunter's canal. Evidently he was disposed to depart "as little as possible" from the old method. He applied a double ligature and tied both portions, but so slightly as only to compress the sides of the artery together. He then applied a second double ligature, lower on the artery, and tied it in the same manner as at first. It is an interesting fact that, in this operation, he included both the artery and vein in the ligatures.

Hunter, it was stated, used four ligatures, and merely tightened them so as to stop the circulation. Home states that "the reason for passing four ligatures was to compress such a length of artery as might make up for the want of tightness, as he chose to avoid great pressure on the vessel at any one part." This practice was in accordance with the prevailing opinion of that period, that arteries were closed by union of the opposed surfaces. The doctrine had come down from Ambrose Paré, and in the use of the ligature this object was especially sought. In various ways the ligature was modified to accomplish that purpose, but for the most part the flat ligature was preferred.

The lessons which Hunter drew from his operation were: (1) that a number of ligatures is not useful, and that one is sufficient; (2) that the artery should not be disturbed further than is necessary to secure the passage of the ligature; (3) that it is not desirable to heal the wound by first intention, but, rather, to allow the cut surface to inflame and suppurate, in order to have it in one's power to reach the artery more readily.

Hunter operated a second time soon after, and applied a single large ligature to both the artery and the vein. He left the wound open to heal by granulation, but his patient died, on the twenty-sixth day, from suppuration and hæmorrhage, due, as he believed, to the open state of the wound. When the hæmorrhage occurred he ligated the artery at a higher point, but without avail. In the third case, he applied a single ligature, and only to the artery; he also closed the wound to secure union by first intention. This case made a good recovery, as did two succeeding cases operated on in a similar manner.

A review of the surgical literature of that period makes it very evident that Hunter's operation was only one step, and by no means a very long one, in the steady advance of improvements in the treatment of aneurism by operative methods. Anel proved that aneurism might be cured by the simple ligation of the artery on its proximal side, without incision of the sac, and thus incurring the dangers of subsequent suppuration. The fault in his operation is, that he adhered to the old method of applying the ligature as near as possible to the tumor, and thus was liable to place it upon a part of the artery partaking of the disease which caused the aneurism, the result of which might be secondary hæmorrhage. Hunter remedied this defect by applying the ligature a little further from the aneurism, and at as short a distance as possible, in order to secure a healthy portion of the artery. He employed the ligature as was practised at that time, with a view of simply compressing the sides of the artery, and securing union by adhesive inflammation. On repeating the operation, he gradually improved in the use of the ligature and finally employed one where he had used four.

It is reported by Home that Hunter's operation was frequently repeated in the London hospitals, but with many modifications. For the most part, the departures from his method were rather toward Anel's operation. Birch used two ligatures, but left the second one loose. Earle applied the ligature above the aneurism, but in the popliteal space. Pott operated in a similar manner. Home, however, followed strictly the method of Hunter, and with marked success. At the close of the century, the merits of the new method were fully recognized, and

pioneers began to venture into new and unexplored regions.

Another step in advance of the old method, and scarcely less important than that made by Hunter, was suggested by Brasdor. This consisted in applying the ligature upon the distal side of the aneurism, instead of the proximal, and leaving the aneurism to consolidate by means of the blood entering the sac. This operation differed slightly, if at all, in its practical effects upon the physiological changes in the aneurism, from the operation of Hunter. It was a most important suggestion, for it enabled the operator to treat successfully a class of cases in which it was impossible to ligate the main trunk on the cardiac side of the tumor. Desault advocated the operation, but Deschamps and Astley Cooper were the first to put the method in practice, the former for a femoral aneurism and the latter for an iliac aneurism. Both failed disastrously. It was not again practised until 1825, when Wardrop applied a ligature to the carotid on the distal side of the tumor, and his patient recovered. Since that date it has become a favorite operation in cases which do not admit of Hunter's method. Mott was the first to operate by this method in this country, his cases being aneurisms of the innominata, for which he ligated the carotid. The first patient was cured, the second died from hæmorrhage. Mott heartily approved the operation, and the success which has since attended it proves his practical sagacity.

The operation of Hunter renewed the discussion, which had long been in progress, relating to the action of the ligature on the artery. As has been stated, the prevailing opinion at the close of the century was that the ligature should simply compress the sides of the artery together, when union takes place by adhesion of the opposed surfaces. This view led to various devices to promote the proper contact of the inner surfaces of the artery. A favorite ligature was made of a number of threads, which was called the "flat ligature." For the same purpose, more than one ligature was employed. Again, compresses were placed under the ligature and on the artery.

In 1803–4, a very original and exact series of experiments was performed by Dr. J. F. D. Jones, then a recent graduate of the Edinburgh school, for the purpose of determining the exact changes which a ligature effected on an artery. The most important conclusions from these experiments were: (1) that when the ligature is properly applied, it cuts through the internal and middle coats, and brings the wounded surfaces together; (2) that an inflammation is excited of the internal and middle coats which gives rise to an effusion of lymph, by which the wounded surfaces are united and the canal rendered impervious; (3) that an ulceration of the external coat follows, and thus there is produced a complete obliteration of the canal of the artery.

Though these propositions were combated by many authors, they greatly influenced leading surgeons, and finally came to be the prevailing belief, and continued to govern practice down to the antiseptic period.

The second notable incident of that discussion is the paper of Mr. Lawrence, in 1814, advocating the use of a very fine silk ligature, and cutting off both ends of the ligature. Hitherto, vegetable matter had been used, as, for example, hemp. It was now proposed to use animal matter, and silk was selected in the belief that it would soften and dissolve in such a manner as to be carried away by interstitial absorption. Mr. Lawrence proposed to apply a small ligature, close the wound, secure union by the first intention, and leave the ligature to be absorbed. He selected a fine quality of dentist's silk, and employed in each ligature the smallest amount possible to tie the artery. He says: "The method I have adopted consists in tying the vessels with fine silk ligatures and cutting off the ends as close to the knot as is consistent with its security. Thus, the foreign matter is reduced to the insignificant quantity which forms the noose actually surrounding the vessel, and the knot by which that noose is fastened. Of the silk, which I commonly employ, a portion sufficient to tie a large artery, when the ends are thus cut off, weighs between $\frac{1}{250}$ and $\frac{1}{80}$ of a grain; a similar portion of the thickest kind I have tried weighs $\frac{1}{20}$ of a grain, and of the slenderest $\frac{1}{1000}$." Mr. Lawrence states that "during the last ten months I have employed this method of securing the arteries in ten or eleven cases of amputation, in six operations on the breast, and in the removal of two testicles." With but one exception, the cases all did well, the wounds healed readily, and nothing was seen of the ligatures. Silk was now more frequently employed, but it was soon discovered that the ligature did not dissolve, and hence remained to cause future irritation and suppuration. While silk came to be preferred as a ligature, the method of Lawrence in closing the wound was not approved.

It is quite remarkable that Mr. Lawrence's suggestion caused no change in practice. He fairly anticipated the antiseptic or aseptic period, and the success of his method commended it to the favorable notice of every operator. It was, however, rejected or unheeded, and the method of Jones continued to be the favorite operation half a century longer, viz., the single ligature with one end depending from the wound. Mott rejected Lawrence's method with the remark: "The absurdity of it consists in this, that the wound will be healed by the first intention, and the ligatures, by being left to remain as an extraneous substance, will, in the course of five or six weeks, manifest their injurious action by producing suppuration." This practice, he thought, was the other extreme of Scarpa's, who kept the wound constantly open.

Dr. Physick, of Philadelphia, seems to have been the first to recommend strictly animal structures for ligatures. He selected deer-skin, chamois, and catgut, and Dr. Dorsey employed them frequently.

A more remarkable contribution to the improvement of the ligature was made by Dr. Jameson, of Baltimore. He made a large number of experiments with various ligatures, and his conclusions completely anticipated the antiseptic period in everything except the use of positive antiseptic materials. He used a very soft deer-skin, cut into fine strips, which had the form of the old flat ligature. This ligature he applied with only sufficient firmness to press the sides of the artery together, and was careful not to divide the coats of the vessel. His purpose was to disturb the artery as little as possible, and especially not to injure the vasa vasorum, as he

relied upon the organization of lymph about the ligature to close the vessel permanently. He alleged, as a result of his experiments and observations upon animals, that when an animal ligature is applied, a capsule will surround the ligature so as not to disturb capillary vessels, or the vessel will be surrounded by an abundance of lymph, the ligature will be dissolved, and will not require removal. It is stated of Dr. Jameson's practice that for many years he used the deer-skin ligature in amputations—the ligature of the carotid, iliac, femoral, radial, and other arteries—and never had secondary hæmorrhage. In what exact terms he describes the appearance of an artery some time after it has been ligated with a catgut ligature antiseptically, will appear when I speak of the present period.

The difficulty of passing the ligature around the artery, owing to the want of a suitable instrument, was a great embarrassment to the early surgeons. Some operators used a probe with an eye, others selected curved needles. At length instruments began to be devised, and many of them are now objects of curiosity as specimens of human ingenuity. The first really useful instrument was devised by Drs. Physick and Hewson, of Philadelphia. This needle was used by Mott in ligating the innominata, and highly commended by him. He subsequently improved it by attaching the needle to the handle by a screw, by means of which the handle could be removed when the needle was under the artery. This he called the "American needle," and it is still the best in use.

Among the visitors at the public hospitals of London in 1784–1786 was Dr. Wright Post, of New York. He was a recent graduate of medicine, and had been a pupil of Dr. Richard Bailey, one of the leading surgeons of New York. Dr. Post was a man of acute observation, and had an ambition to excel in surgery. There is little doubt that he was present at St. George's Hospital on that memorable day in 1785 when Hunter tied the femoral, and that he drew from it the inspiration which led to his future achievements in this field of practice. On his return he became a lecturer on surgery in the Columbia Medical College. Mott, who was his pupil, states that, long before Sir Astley Cooper operated on the carotid, he heard Post in his lectures assert his belief that not only one carotid might be tied for aneurism, but that both might be interrupted by ligatures, on the same person, and the patient recover.

About the year 1794–1795 Dr. Post applied a ligature to the femoral artery on the plan of Hunter. This case has never been tabulated, and is alluded to incidentally in his report of the case of inguinal aneurism for which he ligated the external iliac, and by Mott, in his biography of Post. The patient had a femoral aneurism, caused by a wound of the artery fifteen years previously. The precise location of the aneurism is not given, nor the point at which the ligature was applied. He states that the patient recovered from the operation in about the ordinary time, and the tumor gradually diminished until it was reduced to a size not exceeding one inch in diameter. But the remarkable fact connected with it, to which he makes special allusion, was the continuance of the pulsation in the tumor. This he attributed to the increase in the size of the anastomosing vessels, due to the long continuance of the aneurism. The circulation in the aneurism did not interfere with the gradual diminution of the tumor. He says: "The limb, which had been rendered wholly useless to him by the immense size of the tumor and the extreme pain which he had suffered in the later stages of it, recovered its powers in a reasonable time, and he has continued to use it in all the ordinary exercises of walking, riding, etc , with as much freedom and as little inconvenience as before the disease took place."

Mott, alluding to this case, states that the man was living thirty years after the operation. This was the nineteenth recorded ligation of the femoral after Hunter's first operation, and the first operation by the new method in this country. It was also the first instance of a discussion of a return of the pulsation in the aneurism after ligature of the artery, with a correct appreciation of the cause of such pulsation.

On January 9, 1813, Dr. Post ligated the common carotid artery for aneurism successfully. This was the fifth operation on the common carotid, and the third successful case. It was the first operation in this country for aneurism. In this case Post passed two ligatures around the artery, about three-quarters of an inch apart, and divided the artery between them. He also passed the needle through the artery, as recommended by the younger Cline, to prevent the ligature from slipping from the end of the artery.

The practice of applying two ligatures, and dividing the artery between them, dates back to Fabricius, of the seventeenth century, but was warmly advocated by Abernethy, and practised by him. The danger of hæmorrhage from the slipping of the ligature from the end of the artery was, at that time, regarded as very great, and to prevent it a needle was placed on the ligature after it was tied, and the thread was passed through the artery close to the ligature and tied with the knot already made. This expedient was first recommended by Dionis, and not by Cline, as stated by Post.

The patient recovered from the operation, but the aneurism opened after eight months, and a large hæmorrhage occurred. This hæmorrhage was repeated about six weeks later, when the entire contents of the sac appeared to be discharged, and healthy granulations sprang up. The recovery was now rapid and complete.

One year later, viz., January 4, 1814, Dr. Post applied a ligature to the external iliac for inguinal aneurism. The method of operating was interesting, for at that period no very definite rules had been fixed. He describes his operation as follows:

"An incision was made through the integuments with some degree of obliquity, between three and four inches long, beginning a small distance above the tumor, and extending upward externally to a middle line between the umbilicus and superior anterior spinous process of the ilium. The abdominal muscles were then cut through, until the peritoneum at the lower part of the wound was fully exposed. I next endeavored to detach this membrane from the crural arch so as to get at the artery without opening into the cavity of the peritoneum; but in this attempt I was frustrated. The strength and thickness of the peritoneum at this part were considerably greater than natural, and its adhesion to the ligament so firm that the separation, which is ordinarily so easily

effected, was found in this case altogether impracticable. This condition of the parts may reasonably be ascribed to the pressure of the aneurismal tumor. To arrive at the artery, therefore, under these circumstances, it was necessary to cut through the peritoneum, and thus expose the patient to the additional hazard of inflammation of this membrane, to which it is generally supposed to be very liable when an opening is made into the common cavity of the abdomen. But to accomplish my object there was no alternative. I did not hesitate, therefore, in proceeding with the operation in this manner."

He had great difficulty in his efforts to expose the artery and open the sheath, and to avoid enlarging the wound of the peritoneum he passed the needle, armed with the ligature, through the sheath, on the under side, from within outward. He employed a needle suggested by Dr. Physick, and which was used by Dr. Dorsey in his operation on the same artery. The patient made a good recovery.

The noticeable features in this case are:

1. The incision of the peritoneum and free exposure of the abdominal cavity. No harm seems to have followed this treatment of the peritoneum. There are two suggestions which may, perhaps, explain the freedom from peritonitis in this case. The first is that Dr. Post is always spoken of as a man of great fastidiousness as regards his personal appearance and dress; this led to extreme neatness and cleanliness of his hands and of his instruments, and of the details of his dressing of wounds. The second is the fact that, at the close of the first day, the patient was required to take an active cathartic, composed of infusion of senna, manna, and cream of tartar, which produced, according to the record, "frequent and copious dejections." This thorough action of the bowels would tend powerfully, according to present teachings, to remove the accumulating causes of acute peritonitis after incision of that membrane.

2. Pulsation in the tumor returned on the 24th day, and was continuing at the time of the report, three months after the operation, but without any change in the tumor. He raised the question as to the liability of the return of the aneurism, but decided that it would not return, basing his conclusion on his experience in the case of the femoral aneurism previously described.

On the 28th of November, 1816, Post again ligated the common carotid artery for a pulsating tumor of the neck, about which there was a difference of opinion as to its nature. The patient recovered from the operation, but died two years subsequently. The autopsy disclosed a tumor, with no indications of the previous existence of an aneurism. It was this case that Mott often alluded to in his lectures illustrating the difficulties of correctly diagnosing an aneurism from an abscess, or a tumor situated upon an artery. At the consultation of Post, Stevens, and Mott, the question raised was as to its being an aneurism, an abscess, or a solid tumor. Post regarded it as an aneurism, Stevens as an abscess, and Mott as a solid tumor. Stevens proposed to Post the propriety of exploring it by puncture with a lancet. Post responded by handing Stevens a lancet. Stevens declined, and proposed that Mott should explore. He also declined, and Post was allowed to exercise his discretion.

On the 8th of September, 1817, Dr. Post ligated the left subclavian, in its third part, for aneurism of the brachial artery. He employed the needles invented by Drs. Parrish, Hartshorne, and Hewson, of Philadelphia. The patient made a good recovery, though the aneurism ruptured and discharged its contents during convalescence. This was the eighth recorded operation on the subclavian artery, and the third which recovered. It was also the first operation upon that artery in this country by the new method.

It thus appears that at this early period in the history of the new method, Dr. Wright Post applied the ligature to four different arteries successfully, and twice to the carotid. And these were by no means simple and uncomplicated cases. Each case presented more than ordinary difficulties, and one—the external iliac—involved complications which, at that period especially almost uniformly proved fatal. A success like this was not recorded at that time, and has not been surpassed even in these antiseptic days. As already remarked, we can only account for his great and uniform success by the extreme care of the operator in protecting the wounds from the admission of the common forms of septic matter which adhere to the hands, instruments, and dressings.

Of the five operations, Dr. Post was anticipated in this country in but one instance, viz., ligation of the external iliac. Dr. Dorsey, of Philadelphia, operated in 1811, about three years before Dr. Post.

Great as was the merit of Dr. Post as a successful pioneer in this field, he was destined to be surpassed by his student and colleague in the New York hospital, Dr. Valentine Mott. Mott had not only imbibed a strong predilection for surgery by attendance upon Dr. Post's lectures, but he became also a pupil of Astley Cooper at a period when that surgeon was the leading operator in London. Cooper was the first surgeon who applied a ligature to the carotid artery for aneurism. This operation was performed in 1805, but was unsuccessful. In 1808 he repeated the operation successfully, and Mott was present at the operation. He always spoke enthusiastically of this occasion, and evidently was greatly stimulated by it to pursue the study of aneurisms and their treatment.

A few months later, Cooper attempted to ligate the left subclavian between the scaleni muscles, but failed. Mott was present at this operation also, and was deeply impressed with the difficulties of the procedure, and Cooper's skill and candor. Speaking of the operation, Mott states that "after working indefatigably with all his eminent skill and superlative tact for an hour and a half, he (Cooper) abandoned the operation."

On returning home, Mott was well equipped for the great career which was opened before him. His personal qualifications were of a high order. He was, first of all, a laborious student—not so much of books, for few were then to be had, but a student of nature. He performed no operation during his long life that he did not make the subject of careful study and preparation, if the circumstances permitted. Again, he was a very bold operator, and well adapted to be a pioneer. But this boldness was guarded and tempered by a conscientious conservatism. Moreover, his preparation for every operation, and his careful foresight of all possible emer-

gencies, rendered his fearlessness in undertaking operations entirely safe. Finally, he was a remarkably clean person, being even more fastidious in his dress than Dr. Post. It was a remark of one of his contemporaries that, on Dr. Mott's return from Europe, he was so extraordinarily neat in his person that he attracted the attention of every one when he appeared on the streets. This neatness extended to the care of his instruments, which he required should be thoroughly cleaned, not only after each operation, but also just before an operation. How much of his success in the recovery of his patients was due to this practical asepticism we now can only conjecture, but that it had a most potent influence there can be no doubt.

Mott's pioneer work appears in the ligation of the arteria innominata and the common iliac arteries. The application of a ligature to the innominate artery was not only Mott's greatest achievement in operative surgery, but was the most brilliant operation ever undertaken by any surgeon in the history of operative surgery to that date. Nor has it been excelled in this particular branch, if we consider all the circumstances attending the operation. It was by no means suddenly conceived and executed, but was the culmination of years of preparation. He states that "since the publication of Allan Burn's invaluable work on the surgical anatomy of the head and neck, I have been in the habit of showing, in my surgical lectures, the practicability of securing in a ligature the arteria innominata; and I have had no hesitation in remarking that it was my opinion, that this artery might be taken up for some condition of aneurisms; and that a surgeon with a steady hand and a correct knowledge of the parts would be justified in doing it." The proper case presented itself March 1, 1818, and he says, "I could not for a moment hesitate in recommending and performing the operation." Dr. Wright Post, whom he had so often aided, now became his assistant and guide. Though the operation finally failed after giving the most encouraging prospect of success, Mott was not disheartened, but regarded the practicability and propriety as satisfactorily established by this case, and predicted that it would prove to be "the bearer of a message to surgery containing new and important results."

The ligation of the primitive iliac for aneurism was performed March 15, 1827. Gibson had previously applied a ligature to this artery in a case of gunshot wound during a riot, but he simply seized a bleeding vessel with his finger, and applied two ligatures, and found at the autopsy that one was on the common iliac. Mott's operation was executed with his usual care and caution, though it was rendered very difficult owing to the size of the tumor and the adhesions of the peritoneum. The patient made a good recovery, and was living thirty years after. In the practice of other surgeons the operation has proved very fatal. During the twenty-five years following Mott's operation, there were eighteen ligations of the common iliac with fourteen deaths, or upward of seventy-seven per cent.

Mott's experience in the ligation of arteries was very great, and his success was remarkable. For example, he ligated the subclavian in its third part six times, all the cases successful; the common carotid thirty-two times, with five failures; the external iliac six times—two died, one from drunkenness, one from secondary hæmorrhage; the femoral fifty-three times, failures not known. He had but one case of mortification of the extremity, a success which Dr. Blackman attributed to Mott's great attention to details. Fruitful as was Mott's career in great surgical deeds, the application of a ligature to the arteria innominata gave to him his most enduring reputation. He was accustomed to speak of the exsection of the entire clavicle as his "Waterloo operation," but the profession has accorded the highest distinction to the former operation.

Scarcely less remarkable as a triumph of bold and daring surgery was Dr. Kearney Rodgers's ligation of the left subclavian artery within the scaleni muscles, in 1845. Indeed, Mott, who was one of the consultants, opposed the operation at the time and afterward. He admitted that it might possibly "be tied by a careful and well-informed surgeon," but he "considered that it was improper to do so." But Rodgers had been led, as he states, "to investigate the subject with great care, and accordingly gave it my most sedulous attention." He adds, "I had always considered it as a perfectly justifiable operation, and one that a careful surgeon conversant with anatomy could accomplish, if the tumor was of moderate size." The consulting surgeons threw the entire responsibility upon him, and thus rendered the undertaking doubly important to the operator. He was about to attempt an operation which not only such veterans as Mott and Stevens declined positively to sanction, but which leading foreign authorities decided was not possible. Rodgers had before him, as he states, the utterance of Colles, the eminent Irish surgeon who first tied the right subclavian in the first part of its course. His conclusion was stated as follows:

"This operation, difficult on the right, must be deemed impracticable on the left subclavian. For the great depth from the surface at which this vessel is placed, the direct course which it runs in ascending to the top of the pleura, the sudden descent which it makes from this to sink under the protection of the clavicle, and the danger of including in the same ligature the eighth pair of nerves, the internal jugular vein, or the carotid, which all run close to, and nearly parallel with this artery—all these constitute such a combination of difficulties as must deter the most enterprising surgeon from undertaking this operation on the left side."

But Rodgers was a most skilful operator, of great courage and reserved mental force. He assumed the weighty responsibility which his colleagues imposed upon him, and true to his convictions of duty proceeded to execute the trust committed to his care. The operation proved in every respect as difficult as had been alleged, but he was thoroughly prepared for every emergency. The ligature was successfully applied, and for several days everything promised success, but on the thirteenth day a hæmorrhage occurred, and on the fifteenth the patient died. The lesson which Rodgers drew from his operation was that the vertebral artery, and, if possible, the thyroid axis, should be secured by ligature. He says in concluding his report of the case, that though the operation was unsuccessful, he trusts that, "from the knowledge thence derived, we shall be enabled to enlarge our sphere of usefulness and be the means of preserving human life." This was the first

and only attempt that has been made to ligate the left subclavian within the scaleni muscles.

During the quarter of a century preceding 1868 scarcely any improvement is noticeable in the ligature of arteries. The operations of Hunter and Brasdor were applied in a great variety of conditions, but no modifications worthy of note were made. There were, however, many notable achievements during that period in the ligation of arteries. Perhaps the most important was what has been regarded as the successful ligation of the innominata by Dr. A. W. Smyth, of New Orleans, in 1864. In this case the carotid was ligated at the same time, and on the fifty-fourth day the vertebral was also ligated. Another interesting incident in this period was the revival of the old method by Syme. In three instances he succeeded in opening the sac and tying the arteries at the base of the tumor. All recovered.

The part borne by American surgeons in the history of the ligature of arteries is most creditable. They have not only been pioneers in enlarging the boundaries of this field of practice, but they have cultivated it with a degree of success unrivalled even by British surgeons. An examination of the statistics of ligation of the principal arteries during the first three-quarters of the present century proves the correctness of this statement. Of sixteen operations upon the innominata, six were performed in this country, or nearly thirty-eight per cent. Of these operations one American surgeon performed the first, and another the only successful operation. Of thirteen ligations of the subclavian in the first part of its surgical course, American surgeons performed five, or more than thirty-eight per cent. Of these cases, all of which were fatal, an American surgeon alone ligated the left subclavian within the scaleni. A comparison of the operations upon all of the principal arteries exhibits an equally honorable record.

On the 31st of December, 1868, an event occurred which was destined to be the final consummation of all improvements in the ligatures of arteries. It was the occasion of the application of ligatures to the carotid artery of a calf, by Mr. Joseph Lister. The ligatures were of two different kinds, and were applied at an interval of about an inch and a half. The cardiac ligature was composed of three strips of peritoneum from the small intestine of an ox, firmly twisted; the distal thread was made of fine catgut. Both had been treated with a saturated watery solution of carbolic acid. The ligatures were cut short except that one end was longer than the other. The wound was completely closed, and it promptly healed. Thirty days after the operation the parts were examined, *post-mortem*, and the appearances carefully noted. There was an entire absence of inflammatory thickening in the vicinity of the vessel. The knots of the distal ligature had disappeared, and the only indications of the end which had been left long was a black speck, here and there, upon a delicate thread of cellular tissue in connection with the vessel. The cardiac ligature was continuous in structure with the cardiac wall. The short ends had disappeared, but the knot was represented by a soft, smooth lump, in the interior of which, and lying close to the wall of the artery, was a small residual portion of the original knot quite distinct from the living tissue around it. Between the proximal ligature and the heart, the formation of a coagulum had been entirely prevented by a large vessel taking origin immediately above the part tied, which had thus borne for a month the full brunt of the cardiac impulse. Clots had formed on the distal side of the ligature. A more minute examination showed that the fleshy material which had been formed at the expense of the ligature was a beautiful example of fibro-plastic structure, the coarse fibres which mainly constituted it being composed of very large elongated cells, often containing several nuclei, and presenting, in their course, branchings and thickenings of various forms. At the situation of the distal ligature the structure of the vessel seemed entirely unaffected, the middle coat was neither thicker nor thinner than the neighboring parts. The vessel, so far from showing any sign of giving away, appeared to have additional strength from the operation. The encircling ring of new tissues, incorporated with the arterial walls, must have had a corroborative effect.

Some time after Mr. Lister's publication, I had an opportunity to test upon the human subject the practical value of this experiment.

"A man, aged forty years, suffering from cancer of the tongue, tonsil, and pharynx, came under treatment at an advanced stage of the disease. He was extremely emaciated, very sallow, could swallow liquids only and with great difficulty, and spoke in a hoarse whisper. He had recently had several slight hæmorrhages from the region of the affected tonsil, and was very apprehensive lest he should bleed to death, and extremely anxious to have measures taken to prevent its recurrence. Extirpation of the whole or any part of the growth so as to benefit him was impossible without endangering his life. The only operation practicable was ligature of the trunk of the vessel whose branches were distributed to that region—viz., the external carotid. This operation he urged to have performed, and accordingly a catgut ligature, carbolized, was applied. The ends were cut short, and the wound closed. Except a slight formation of pus under the skin, due to imperfect drainage, but having no connection with the ligature, the recovery was prompt, and the patient was soon walking about as usual, the cicatrix becoming firm and depressed.

"He had no more hæmorrhages, but died of exhaustion from inanition six weeks after the operation. The autopsy revealed the following condition of the parts involved in the operation: The common carotid, laid open to its bifurcation, was entirely free and without discoverable change. At the bifurcation, and throughout its extent, the internal carotid was normal and without a trace of injury. Near the origin of the external carotid the calibre of that vessel suddenly diminished, and, a little higher, was completely closed. There was no trace of a clot, and no evidence that there had been a clot. But what attracted most attention was a bulbous enlargement of the artery at the point of ligation, which had the appearance of a large ring of new tissue around the artery. This ring was as hard and dense as a cicatrix. An incision was next made through this structure down to the centre, or to a point corresponding with the centre, of the vessel. The calibre of the vessel was completely obliterated by the firm union of the opposing surfaces. Above this point was a well-formed clot extending to the origin of the superior thyroid. On dissecting a ring of new tissue it was found to be well organized,

and at two points was discovered a fine black substance, one portion being an eighth of an inch long, having a direction transverse to the long axis of the artery. These threads were the only remains of the ligature traceable."

Looking at the specimen as a whole, it was apparent that the results of the application of the ligature in this case had been: 1. The immediate closure of the artery by pressure. 2. No injury to the internal and middle coats. 3. The permanent closure of the artery by the union of the opposing surfaces. 4. The strengthening of the artery, immeasurably, by the formation of an immense ligature of living tissue. 5. The possibility of ligating an artery close to its origin, with only the result of strengthening the vessel at that point.

Commenting upon his experiment, Mr. Lister remarked:

"It appears that by applying a ligature of animal tissue antiseptically upon the artery, whether tightly or gently, we virtually surround it with a ring of living tissue, and strengthen the vessel where we obstruct it. . . . The surgeon may now tie an arterial trunk in its continuity close to a large branch, secure alike against secondary hæmorrhage and deep-seated suppuration."

To one who has been personally familiar with the painful anxiety with which the earlier surgeons watched their cases, especially at the period of the separation of the ligature, such language seems preposterous. But, fortunately, it is true. We have reached the happy era of surgery, when to ligate an artery means to strengthen it at the point of ligation. We can ask no more. The improvements in this branch of surgical practice have attained—PERFECTION.

MEDICAL PROGRESS.

Parotitis due to the Pneumococcus.—DUPLAY, in *La Semaine Médicale* of January 14, 1891, reports an interesting case of parotitis following an attack of pneumonia in a man forty-seven years old. Succeeding all the symptoms of a well-developed pneumonia, there suddenly ensued an enormous swelling in the region of the left parotid gland, with an œdema of the entire side of the face, and accompanied with severe pain, which was increased by pressure or by movement of the jaws. This was accompanied by a rise of temperature and symptoms of general depression. The diseases in which this condition occurs are numerous. It has been observed to follow many infectious diseases, including typhus and typhoid fevers, cholera, eruptive fevers, dysentery, pyæmia, puerperal fever, and, as in this case, pneumonia. The pneumococcus was first discovered by Pasteur in 1879, and investigated by Friedländer in 1882, and, later, by Talamon, Fränkel, and Netter, and is known as the pneumococcus of Fränkel. It is slightly elongated and encapsulated, and is grouped in the form of a diplococcus. It acquires a great virulence by culture, which, however, disappears in a short time—usually by the end of seven days. This is peculiar, especially if we bear in mind that the defervescence in pneumonia usually occurs about the seventh day. This micrococcus not only invades the lungs, but is found in the mouth of many healthy patients, and is usually entirely inoffensive. It becomes virulent, however, under certain conditions which are not yet understood, and gives rise to disease in whatever part of the body it enters. It may pass through the Eustachian tube, and produce an otitis; or into the sinuses, and give rise to a coryza; or, under certain circumstances, it may even enter the cranial cavity and produce a basal meningitis. The digestive tract is rarely invaded by this microorganism. The prognosis of these cases is generally grave, pyæmia usually causing death. However, under modern antisepsis, it is not so invariably fatal as it formerly was. As regards treatment, the strength of the patient must be sustained, and it is well in some cases to make large incisions early, thus aborting the progress of the disease; while, in other cases, to open the pockets of pus as they are formed, is all that will be necessary.

A Mixture for Dissolving Diphtheritic Membranes.—CALDWELL recommends the following solution for this purpose:

℞.—Papain	. . .	2½ drachms.
Hydronaphthol	. .	2 grains.
Hydrochloric acid	. .	15 drops.
Distilled water	. .	3 ounces.
Glycerin	. . .	2 drachms.—M.

This is to be applied to the affected parts by means of an atomizer every half hour.

Antiseptic and Sedative Treatment of Hæmorrhoids.—In the *Revue de Thérapeutique Médico-Chirurgicale* the following treatment, consisting in the employment of chrysarobin with belladonna and iodoform, is recommended by KASSOBUDSKI as an equally useful application in the treatment of internal and external hæmorrhoids. For the internal hæmorrhoids, he prescribes the following:

℞.—Chrysarobin	. . .	15 grains.
Iodoform	. . .	5 "
Extract of belladonna	.	8 "
Cacao butter	. . .	6 drachms.

Of this are made ten suppositories, and one suppository ought to be inserted into the rectum each day. After five or six hours the pain and the tumor diminish. The treatment may continue for several months without harm.

For external hemorrhoids the author recommends washing them with a solution of corrosive sublimate of the strength of 1 to 1000 or of carbolic acid, 1 to 50. After this the following salve may be applied:

℞.—Iodoform	. . .	5 grains.
Extract of belladonna	.	8 "
Vaseline	. . .	1 ounce.

Treatment of Dysentery.—MINORBI, in *L'Union Médical*, describes a method of treatment which he has followed in twenty-three cases of dysentery. In one case a cure was obtained in a very few days. The treatment consisted in the insertion into the rectum of suppositories made in the following manner:

℞.—Naphthalin Cacao butter	} of each	2½ drachms.

Where there is ulceration or any other condition

which tends to make the use of a suppository painful or dangerous, he has recourse to the following injection:

℞.—Naphthalin . . . 75 grains.
Olive oil . . . . 6 drachms.

At the beginning of an attack, when there is a good deal of tenesmus, the injections should be given every half hour, but ordinarily it is sufficient to repeat them three or four times in the twenty-four hours. The advantage of this method is that it does not cause constipation, which opium is apt to produce.

ROSSBACH employs naphthalin in the following manner in this condition:

℞.—Naphthalin . . . 10 grains.
Boiling water . . . 4 ounces.
Decoction of marshmallow 1 pint.

This is to be used as an injection at the temperature of 100°. In children who suffer from diarrhœa dependent upon the presence of parasites in the lower bowel, the quantity of naphthalin which is employed should not be more than 15 grains in 4 ounces of oil.—*L' Union Médicale*, December 7, 1890.

Treatment of Articular Rheumatism by Mercury.—CALALB, of Bucharest, employs the following method in the treatment of acute articular rheumatism: He applies ointment of mercury around the inflamed joint, and surrounds this with gutta-percha, which is kept in place by bandages of tarlatan. This dressing is left undisturbed for four days, and at the end of that time he asserts that the pain completely disappears, or, at least, is very much ameliorated. The application may then be renewed. Care should, of course, be taken that too much mercury ointment is not used, owing to the danger of ptyalism. In eight cases in which the author has resorted to this method he had the most excellent results, and he states that the patients bear the mercury exceedingly well. It is advisable to let them have a gargle of chlorate of potassium and myrrh to prevent any tenderness of the gums.—*Revue Internationale de Bibliographie Médicale*, January 25, 1891.

Treatment of Erysipelas by Corrosive Sublimate.—CAYET, in a Paris thesis, gives a method of treatment which was employed by Talamon in the treatment of the pustules of smallpox and which he has used for the relief of erysipelas. The following solution is applied to the affected parts by means of an atomizer:

℞.—Corrosive sublimate, Tartaric or citric acid } of each 15 grains.
Alcohol . . . . . 1½ drachms.
Sulphuric ether, enough to make 3 ounces.

This solution should not be sprayed into the nostrils and the eyes must be protected. The atomizations are to be repeated two or three times a day, and Cayet asserts that the cutaneous inflammation passes away in four days under this treatment.—*Revue Internationale de Bibliographie Médicale*, January 25, 1891.

The Absorption of Medicaments from Ointments.—Much discussion has arisen as to the rapidity of the absorption of drugs through the skin and as to the best vehicle for bringing them in contact with the body. Lanolin has been highly praised, and vaseline has been thought to be a non-absorbable substance which should not be employed. On the other hand, LUFF has reached the conclusion that the best ointment for the promotion of absorption is vaseline. He employed iodide of potassium, carbolic acid, and resorcin mixed with vaseline, and with lard or lanolin, and examined the urine of the patients to determine how rapidly the drugs were absorbed and eliminated. The absorption of iodide of potassium, according to this series of tests, is as follows: When mixed with vaseline, it appears in the urine in one hour; when mixed with lard, in nine hours, and when mixed with lanolin, not at all. Carbolic acid, when mixed with vaseline, appears in the urine in two and a half hours; when mixed with lard, in five hours, and when mixed with lanolin does not appear at all. In the case of resorcin and vaseline, the drug was recovered from the urine in ten hours; when mixed with lard, in fifteen hours, and when mixed with lanolin, not at all. Further tests also showed that drugs mixed with lanolin did not appear in the urine even after twenty-four hours.—*Revue Internationale de Bibliographie Médicale*, January 25, 1891.

Treatment of Malignant Pustule.—In the treatment of malignant pustule, CASSON has employed with success subcutaneous injections of bichloride of mercury. In one case there were four pustules, and into each of these he injected strong solutions of corrosive sublimate. The pain which followed the injection disappeared after the first use of the drug. At the same time that these injections were employed the surface of the pustule was dressed with lint soaked in a strong solution of the corrosive sublimate.—*Revue Internationale de Bibliographie Médicale*, January 25, 1891.

The Duration of Pregnancy.—OLIVER concludes, after very careful observation, that the duration of pregnancy in the human female varies as much as it does in the case of many of the lower animals. Issmer, reckoning only cases in which the fœtus was well developed, asserts that the duration ranges from 260 to 304 days. But Oliver believes there must be some error in this statement. If we reckon from the last menstruation, we must be careful to ascertain the exact date of the cessation of this, for it will be remarked that where the duration of the discharge varies little, the woman, when asked, is more likely to give the date of beginning than the date of cessation of the last menstruation, and in this way mistakes may arise in our calculation to the extent of four or more days. The majority of authors are agreed that in reckoning the duration of pregnancy in woman, we ought to fix the probable date of delivery on the 278th day from the cessation of the last menstruation. He is of opinion that the best results will be obtained by ascertaining, first, the date of the cessation of the last menstruation, and then the usual duration of the inter-menstrual period in each given case; the number of inter-menstrual days should then be divided by two, and it will be found that the 260th day from the middle of the inter-menstrual period will most probably be the date of confinement. — *Liverpool Medico-Chirurgical Journal*, January, 1891.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage in North America.

Per Annum, in Advance . . . . . $4 00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, MARCH 14, 1891.

THE INFLUENCE OF SWEET OIL ON CHOLELITHIASIS.

The *Medical Record* notices editorially an interesting discussion of the Medical Society of North Carolina upon the influence of sweet oil on the removal of gall-stones. The discussion subsequently appeared in the *North Carolina Medical Journal*. The subject might seem to have been sufficiently studied for some definite opinion to be reached as to the utility of this remedy, and yet, judging from our contemporary's remarks, chaos still prevails—at least in North Carolina. The conclusions arrived at, if, indeed, it may be said that any were reached, are quite at variance with those now generally received in this country and abroad. They are, briefly, that sweet oil relieves gall-stone colic and prevents its recurrence rather by some modifying influence upon the duct and adjacent bowel than by any effect in expelling the stone. Yet it is mentioned that the President of the society described the case of a man who had three attacks of hepatic colic, each of which oil relieved. The gall-bladder at each seizure was much distended with bile and a stone a half-inch in diameter could be distinctly felt in the gall-bladder. Under the influence of oil the gall-bladder expelled the bile but the stone could still be felt within it. As colic could scarcely be caused by a calculus in the gall-bladder, the non-expulsion of this concretion practically had no bearing on the case. Each attack was, in all probability, due to a similar concretion lodged in the common bile-duct, and which was floated into the bowels under the influence of the oil. This fact does not seem to have been grasped either by those who took part in the discussion or by our contemporary, for it appears that this case was narrated to demonstrate that oil relieves colic in some mysterious way without striking at the cause.

There is no question that the usual cause of hepatic colic is the presence of a gall-stone in one of the biliary ducts—hepatic, cystic, or choledochus; and there seems no doubt that, in a very fair proportion of cases, sweet oil does effectually check colic and prevent its recurrence. Abundant testimony now exists as to this, and it has come to be generally accepted that sweet oil acts as a cholagogue, and that when gall-stones are present in the ducts it tends to promote their extrusion. The distinguished therapeutist Germaine Sée recently, in *La Médecine Moderne*, strongly advocates but two remedies for the relief of cholelithiasis, sodium salicylate and olive oil. Clinical experience with the latter causes him to believe that it both promotes the expulsion of gall-stones and relieves the attending pain and jaundice; though he accepts the results of Rosenberg's experiments on dogs, which show that sweet oil decidedly increases the outflow of bile, especially of its more fluid portions, and that this increase is synchronous with the formation of an excess of fatty acids, he is unable to explain these effects.

The only plausible theory yet offered to account for the efficiency of the oil is that advanced by Dr. D. D. Stewart in a contribution to The Medical News (November 23, 1889), and we are somewhat surprised that it has not received wider notice.

Having in mind that oils and fats are decomposed in the duodenum into their fatty acids and glycerin, it occurred to Dr. Stewart that glycerin so formed probably has the same action in the duodenum as in the rectum when used as a laxative enema, withdrawing water and causing hyperæmia and irritation of the afferent nerves, thus leading to energetic reflex contraction of the gall-bladder, and cystic and common bile-duct. Hence concretions therein sufficiently small to be expelled, are rapidly passed into the duodenum. He suggested also that the diffusive power of glycerin might enable it to enter the ductus

communis and even the cystic and hepatic ducts, and perhaps reach the gall-bladder and the liver, producing a similar depletion of the vessels there and reflexly exciting the muscular fibres of these ducts to contraction, thus probably causing an outflow of dilute bile which would assist in expelling the stone. In the two cases in which Dr. Stewart used oil, gall-stones were recovered from the fæces in addition to quantities of soapy concretions. Noting the smooth, apparently eroded appearance of several of the stones, it occurred to him that the warm solutions of soap formed by the decomposition of the oil might exert a solvent action on cholesterin stones and in some instances cause their disintegration in their passage through the intestines. He found that a solution of soft soap had a very solvent effect on a portion of an old cholesterin stone placed in it. He thought that this might, in a measure, account for the failure to find gall-stones where search had been properly made in cases of hepatic colic treated by large doses of oil. It is worthy of note, that Rosenberg states that fatty acids also are capable of dissolving cholesterin.

Should this plausible theory of Dr. Stewart's be confirmed by experiment, the treatment of hepatic colic may be pursued on a more intelligent basis than hitherto. Glycerin might be administered in gelatin capsules in place of oil, the capsule being used to prevent the dilution of the glycerin before it reaches the duodenum. Or should oil be preferred, pancreatin, in capsules, might be simultaneously administered to insure its complete splitting up.

UTERINE RETRO-DISPLACEMENTS.

As is usual with most ailments of the human body, the treatment of retro-displacements of the uterus has undergone many changes; in fact, the evolution is still progressing. The method of replacing the uterus and retaining it in its proper position by the aid of pessaries is one of the oldest and the one to which the profession has most constantly resorted. During the past few years, since surgical procedures have taken such a prominent position in the treatment of diseases of women, many plans based on surgical principles have been devised and put to trial. The mere number of these operations demonstrates how unsatisfactory any and all of them have proven. Had the results of one of them been even approximately satisfactory, the profession would not be slow to adopt it; the fact that none of them has been generally acceptable is but another indication that they do not fulfil all that is promised for them. Rabenau's method of excising a wedge-shaped piece from the anterior lip has been universally abandoned on account of its inefficiency. Both electricity and Thure-Brandt's method of massage have been enthusiastically praised and then forgotten. The Alexander-Adams operation of shortening the round ligaments extra-peritoneally and stitching them to the inguinal canal, has been a matter of active controversy. Although some few surgeons seem to get good results from it and report long series of successful cases, yet it fails to appeal, in ease of performance and permanence of results, to the vast majority of the profession. Edebohl's modification of splitting open the entire length of the inguinal canal seems to promise greater ease and certainty in the performance of the operation itself, but gives no promise of better results. The method proposed by Schuecking of passing a suture through the anterior wall of the uterus *per vaginam*, bringing the end out again into the vagina and then tying the two free ends, has fortunately not been adopted in this country. Schuecking himself reports that a number of his cases had bloody urine after the operation. The results of such procedure must in the long run be disastrous. The method of opening the peritoneal cavity and stitching the fundus to the abdominal walls, contributed by German surgeons, with or without scarifying the surfaces to be united, for a time gave promise of permanent good and was most enthusiastically recommended in this country. It was not long, however, before failures began to be noted, and finally the abdomen had to be reopened for the purpose of undoing the mischief created by the operation. The operation proposed by Wylie, of doubling the round ligaments intra-peritoneally upon themselves and stitching them in that position, as well as the modification of this procedure proposed by Dudley, of denuding the round ligaments and stitching them to a denuded surface on the anterior aspect of the uterus, although extremely ingenious, has not found many advocates.

Kelly, at the meeting of the American Gynecological Society in 1889, proposed the following operation, but abandoned it later for the reason that all his cases had proven failures. The operation consisted in pushing the uterus up *per vaginam* until the fundus could be seen impinging upon the

abdominal wall. A curved needle was then carried through the skin and the fundus of the uterus, together with all the intervening tissues. It was brought out again at a point directly opposite the point of entrance. The two free ends were then tied. Krug (*New York Medical Journal*, January 3, 1891) modifies this procedure by cutting through all the abdominal tissues until he reaches the peritoneum. With the uterus lifted up from the vagina and a finger in the wound, a needle is passed through the whole thickness of the abdominal wall. The point of entrance of the needle is on the skin surface, a quarter of an inch from the incision. With the cutting edge of the needle, guided by the finger in the wound, the uterus is scarified on its anterior surface to the extent of about a square inch. The needle is finally carried through the fundus and brought out through the abdominal walls at a point opposite the point of entrance. Two such sutures are introduced and when the free ends are tied the wound is closed. The advantages claimed for this method are that the peritoneal cavity is not opened and at the same time the denudation is safely performed. The author reports six cases operated upon by this method, but the time is too short to be able to judge as to the permanency of the results.

Krug distinctly says that this operation is only applicable to cases in which the retro-displacement is uncomplicated. This is equally true of all the operations in which the peritoneal cavity is not opened, and just here lies the great fault of all such procedures. It is exceptional that an uncomplicated retro-displacement causes any trouble, and it will be frequently found in cases in which there is no local complication that the trouble is a general one, with a local manifestation of symptoms. If there be really no local complication the uterus can readily be replaced and held in position by a properly-fitting pessary; consequently the foregoing operation, with all its kind, would seem to be superfluous. If, on the other hand, there are adhesions present, all these extra-peritoneal operations must of necessity fail. Experience has shown that the intra-peritoneal methods have accomplished little more. The normal position of the uterus is in the pelvic cavity and all attempts to bring and retain it in the abdominal cavity are irrational and must fail. For uncomplicated cases the risks of a serious operation should not be taken, especially as the pessary is at our command. If the uterine appendages are diseased, the shortening of both the round and broad ligaments incident to the removal of the appendages will in itself correct the malposition. If the only complicating trouble be adhesions of the fundus, without any disease of the tubes or ovaries, the most rational procedures would seem to be outlined in the principles advanced by Wylie and Dudley.

REVIEWS.

A Text-book of Hygiene from an American Standpoint. By G. H. Rohé, M.D. Second edition, thoroughly revised and largely rewritten, with Illustrations and Tables. Philadelphia and London: F. A. Davis, 1891.

Notwithstanding the fact that the Illinois State Board of Health requires practitioners who come within its jurisdiction for the purpose of practising medicine to have attended lectures upon the subject of hygiene, very much less attention is given to this branch than necessity requires; and the fact that the entire subject has been so abused by those who are quacks, or exist on the borderland of quackery, has caused certain members of the profession to regard with distrust those who devote themselves to the study of Preventive Medicine. These objections, however, do not obtain against the book which has been prepared by Dr. Rohé. Not only is the advice which it contains of practical utility but it is so put that "he who runs may read," and profit by it. The article on the "Influence of Cooking upon Food" and that on "Beverages containing Alcohol" are unusually good and fully up to the times. The recommendation is made that American wines should be used in place of the imported wines which are, for various reasons, in many cases greatly adulterated. A very considerable addition to the book is the article upon "Quarantine," by Dr. Walter Wyman, of the United States Marine-Hospital Service, and the contribution of Dr. Albert L. Gihon, of the United States Navy, upon "Naval Hygiene." Very few of the profession appreciate the measures which are taken by the various branches of the government service to protect the inhabitants of the United States from disease, and all articles which can bring this subject to us in a forcible manner are worthy of being carefully considered. The fact that Dr. Rohé's book has passed into a second edition shows that it has been appreciated, and as he has taken pains to make the second edition much more thorough and has added a hundred pages to the volume, those who are interested in hygiene should certainly possess it.

The Daughter: Her Health, Education, and Wedlock. By William M. Capp, M.D., F.A. Philadelphia and London: F. A. Davis, 1890.

Dr. Capp has written a book which will doubtless be found useful by those physicians who think it advisable to place in the hands of patients information concerning the care of themselves or their children. The author, very properly, does not profess to do anything more than to direct the laity in that knowledge which is

so necessary for their welfare. Many of the more delicate subjects such as that of "Training for Married Life," the "Interruption of the Menstrual Function," and the "Relationship between the Sexes" are treated with very considerable skill and in a manner which could not strike anyone as being improper or bald. There is probably no period of a woman's life in which the possibilities for disordering natural functions are greater than they are about the age of puberty, and the absolute ignorance in which most young girls are allowed to exist, even until they attain adult life, is often productive of much misery, both mental and physical. Quite a number of the books which have been written by physicians for popular use have been prepared in such a way that the professional man can read between the lines strong bids for popular favor, or terms are employed which are so deep as to give no information or produce great alarm. These objectionable features will not be found in Dr. Capp's *brochure*, and for this reason it is worthy the confidence of physicians. Certain portions of the book seem to point to the fact that the author has been more alive to the importance of the subject than to the character of the English which he has employed; thus, on page 99, the typographical error which reads "nominal health," has been, by the use of a pen, changed to the words "normal health," the adjective (normal) being, of course, absolutely unnecessary.

A Treatise on the Diseases of Infancy and Childhood. By J. Lewis Smith, M.D. Seventh edition, thoroughly revised. Illustrated. Philadelphia: Lea Brothers & Co., 1890.

To those who are interested in children's diseases the appearance of the seventh edition of Dr. Smith's classical work on this branch of medicine has given much pleasure, because it brings the book fully up to date and renders it even more than before worthy of universal recommendation to both students and practitioners. As the author points out in the preface, he has found it necessary to include for the first time the discussion of a number of diseases which hitherto were not considered by him. Prominent among these are epilepsy, appendicitis, typhlitis and perityphlitis, and an article on intubation, all of which subjects are of great importance and worthy of a place in so complete a text-book. Most of our readers are so well acquainted with Dr. Smith's book in former editions that to do more than direct attention to the seventh revision is unnecessary.

CORRESPONDENCE.

CHICAGO.

The Chicago Policlinic will commence its third semi-annual special course for practitioners March 30th. Among the lecturers are Drs. Fenger, Parkes, Belfield, Etheridge, and Senn.

That too great care cannot be exercised in writing prescriptions was well illustrated in the case of a prominent physician in this city who recently prescribed an overdose of laudanum for a twelve-weeks-old baby, the child dying in a few hours thereafter. It is said that the dose was large enough to kill three ordinary men. The doctor was sued for $5000, but the jury returned a verdict for $500 damages. The case has attracted considerable attention from medical men and pharmacists. The doctor, discovering his mistake, called at the drug-store shortly afterward, and securing the prescription, changed it in order to make it appear that the medicines called for were harmless. This fact was brought out in the evidence given in the case.

The grand jury reported a few days since that, after visiting the Detention Hospital, they had found it, after careful investigation, to be clean and free from vermin. With regard to the Cook County Hospital, they had examined closely every department, particularly the food and the hygienic surroundings, and found them in good condition. The food was well cooked and of wholesome quality. The report states, also, that there are 400 patients at the county hospital, and all well cared for, both officers and attendants being kind and considerate in their treatment. The Asylum contains 1299 men, 425 women, 50 girls, and 45 boys. The building is kept scrupulously clean, and everything possible for the best interests of the patients is done.

RETROVERSION OF THE UTERUS, WITH THE BLADDER ADHERENT TO THE ABDOMINAL WALL.

To the Editor of The Medical News,

Sir: The writer was called in consultation, on January 3, 1889, by Dr. Willoughby, of Buffalo, to see Mrs. McC., forty-one years of age, the mother of five children, the youngest being four years old. The history of the case, as given by Dr. Willoughby, was as follows: About a week before our consultation he was called, and found the patient suffering from headache, loss of appetite, nausea, pain in different parts of the body, insomnia, and difficulty in urinating. During the previous two or three days she had had a sanguinous discharge, although not so much as during her normal periods. She had not menstruated for three months, yet previously to that time her menstrual periods had been regular. Dr. Willoughby concluded that she was pregnant but threatened with a miscarriage, and treated her accordingly. The flow soon stopped, but the patient did not improve, and, upon a more thorough examination, he discovered, in addition to her other troubles, that she was suffering from cystitis and that the fundus of the retroverted uterus was low in the hollow of the sacrum, the os being high behind the pubic arch; also, that she passed but little urine and this with great difficulty. It was found necessary to introduce a rubber male catheter the full length of the instrument to empty the bladder. Thinking that the retroverted uterus pushed the bladder up out of position, thus increasing the difficulty in urinating and also aggravating the cystitis, an effort was made to replace that organ, but without success.

On the next day I was called, and found the patient in bed. Her expression was somewhat anxious, pulse rapid, and temperature 101° F. There were slight abdominal pain and tenderness, and no appetite, and her bowels were constipated. After a thorough examination I fully concurred with Dr. Willoughby in his diagnosis. As

we both thought it advisable to replace the uterus, if possible, the patient was put in the knee-chest position. The vulva and vagina being capacious, I could introduce my hand and grasp the uterus, yet, after persistent effort, was unable to restore the organ to its normal position, or even to move it, and the attempt had to be given up. The patient experienced no ill-effects from the manipulation, but she gradually sank, and died a week later. An autopsy was made by Dr. Willoughby in the presence of Dr. Cronyn and the writer, eighteen hours after the patient's death. Upon making an incision through the abdominal wall, the bladder, which was partly filled with urine, was opened, owing to the fact that its whole anterior wall was closely adherent to the abdominal wall over a nearly circular area six or seven inches in diameter, the upper border of the adhesion being two inches or more above the umbilicus. The adhesions were quite firm, requiring considerable force to separate them. The posterior wall of the bladder was adherent to the uterus for a short distance, and there were two or three points of adhesion between the anterior and posterior walls of that organ. The fundus of the retroverted uterus was situated low in the hollow of the sacrum, and contained a normal fœtus of about three and a half months development. The liver and kidneys were engorged with blood, but the other abdominal organs were healthy.

The point to which I wish to call attention is the firm, extensive, and high adhesions of the bladder to the abdominal wall. In my experience this is an unusual complication, yet it readily explains why the retroverted uterus could not be replaced.

Henry D. Ingraham, M.D.
405 Franklin Street, Buffalo, N. Y.

BELLADONNA FOR STRANGULATED HERNIA.

To the Editor of The Medical News,

Sir: In your issue of January 31st, under "Medical Progress," you quote from an article of Hayem in the *Centralblatt für Chirurgie*, on "The Treatment of Strangulated Hernia by Belladonna and Atropine."

I write to say that since 1865 I have used the Unguentum Belladonnæ, of the U. S. Pharmacopœia, as an inunction to the tumor in cases of strangulated hernia, to facilitate the taxis of the contents of the hernia, and always with success.

I reported the method to several medical societies, and it has been used successfully by some of my former students. Yours truly,

Faneuil D. Weisse, M.D.
New York, February 26, 1891.

DIGESTION, ASSIMILATION, AND OXIDATION.

To the Editor of The Medical News,

Sir: In reply to the criticism by George L. Amerman, in The Medical News of February 28, 1891, for which I am very thankful, permit me to say that one of the sentences to which he refers should read as follows, to make my meaning clear: "This action is effected" *not* "only" *in* an "alkaline solution," *but also* "in an acid medium the percentage-acidity of which has not exceeded ten per cent." This, I think, would also imply action in a neutral medium, possibly developed in the stomach, between the entrance of the salivary fluid from the mouth and the final arrest of the action of the ptyalin by the supra-acid fluid developed within the gastric cavity. I did not lay much stress upon the fermentative action in a neutral medium, because of the little proof that such a reaction is developed and maintained for any considerable length of time in the stomach during the natural processes of digestion.

In the experimental laboratory no one can deny a given result, but evidence obtained in a glass test-tube, or as the result of experimental work upon the lower animals, is not always positive proof of an identical action in the laboratory of the human system.

No one can appreciate more highly than I the evidence obtained in the laboratory, but it will not always correspond with clinical results, because the conditions are not absolutely the same, and in all cases due allowance must be made on both sides if the maximum amount of knowledge is to be attained.

Second: In reference to the terms *non-nutritious* and *nutritious*, as applied to the two classes, CHO and CHNOS compounds. Until the chemist has clearly proved that the chemico-physiological laboratory of the animal economy is capable of taking a simple CHO element, and joining free nitrogen to it, and thus developing within the system a proteid substance, it seems to me proper to retain and follow this classification, as it so closely defines our meaning. The terms "*essential*" and "*accessory*," used by Mr. Huxley, practically mean about the same thing, but they are much less explanatory, and cannot be used with such force, where we apply these laws in the development of diseased conditions as I frequently do in my lectures.

Third: In reference to "the *nitrogenous* envelope surrounding the starch granule." This is unquestionably misleading, and I am glad of the opportunity for correcting the misapprehension. A glance, however, at Table VI., in Lecture III., will show that cellulose is not credited with containing nitrogen, but is rated as a purely CHO element. So that the statement refers to the starch-bearing substance as a whole, and not to purified starch alone. The statement, to obviate all doubt, ought to have read thus: The nitrogenous or proteid part of the starch-bearing substance is digested by the peptic action in the stomach, thus setting free, as it were, the granulose and cellulose, which places the starch granule in a favorable position to imbibe water, to swell up, and in part liberate the granulose from the cellulose.

In regard to the "dogmatic" assertions as to what ferments are, I fully appreciate that, in a measure, what we say about them is largely theoretical, but until more positive information upon the subject is developed, it seems but wise to use these positive statements regarding terms that are in common use, like ptyalin, pepsin, etc. Because Foster says probably other bodies are active constituents, but fails to tell us what they are, why should we confuse our minds with a thousand and one things that may possibly be discovered in due time?

It was in the attempt to base practical medicine upon scientific fact that these lectures were written and delivered in this positive style, and just so soon as the physiological chemist will tell us positively which of the

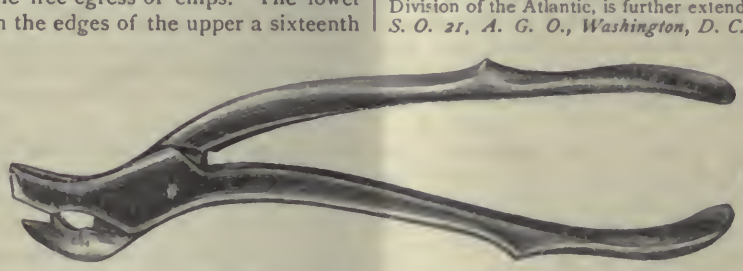
probable ferments is to be the exact starch-transforming substance, and get it so placed or arranged that it will correspond with clinical observations, it will be accepted at once, and I am sure that my fellow-students in this great field will gladly welcome this more definite information. WILLIAM HENRY PORTER, M.D.

NEW INSTRUMENTS.

SPINAL RONGEUR FORCEPS.

BY WILLIAM BARTON HOPKINS, M.D.,
OF PHILADELPHIA.

THE forceps here exhibited are designed to open the spinal canal midway between the spinous and transverse processes. The instrument consists of an upper cutting blade and a lower jaw which acts as a counter, as in the cranial rongeur forceps devised by the writer some years ago. The upper blade has upon its lower margin a double cutting edge an eighth of an inch wide, and is fenestrated with an opening larger at the top than below, to allow of the free egress of chips. The lower blade enters between the edges of the upper a sixteenth



of an inch, and will therefore cleanly incise dense fibrous tissue as well as bone. The lower jaw has a gradual bevel from before backward in order that it may follow in its track without binding; a shoulder at its heel acts as a gauge to indicate the depth it occupies in the bone. The whole instrument has an S-shaped curve that it may be more readily manipulated in the bottom of deep wounds, but care has been taken to preserve the parallel between the axis of the blades and that of the handles. The handles are made with stops to give good purchase in thrusting the instrument forward. The requirements which it has been sought to fulfil with this instrument are, first, to enter the continuity of the spine and divide the laminæ with a single instrument; second, to make a clean narrow bone-wound which can be approximated if desired; third, to lay bare an extensive portion of the cord with rapidity and without risk of injury to it or its membranes. "Experimenting upon the cadaver they are found to enter the spine at any point (cutting always from below upward) with great ease, and with them sixteen laminæ at the dorsal spine were cut away, exposing the cord in eight vertebræ, in seven minutes." Though intended particularly for the spine, its probable adaptability for craniectomy has not been lost sight of.

State Board of Medical Examiners and Licensers.—The following resolution is self-explanatory:

Resolved, That the Faculty of the Woman's Medical College of Pennsylvania approves of the present bill of Hon. Frank M. Ritter to establish a State Board of Medical Examiners and Licensers.

CLARA MARSHALL,
Dean.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 3 TO MARCH 9, 1891.

By direction of the Secretary of War, leave of absence for two months, on surgeon's certificate of disability, is granted SAMUEL HORTON, *Major and Surgeon.*—Par. 7, *S. O. 49, A. G. O., Washington. D. C.*, February 4, 1891.

By direction of the Secretary of War, HENRY LIPPINCOTT, *Major and Surgeon*, is relieved from duty at Fort Union, New Mexico, to take effect upon the final abandonment of that post, and will then proceed to Fort Adams, Rhode Island, and report in person to the commanding officer of that post, for duty as Post Surgeon, reporting by letter to the commanding general Division of the Atlantic.—Par. 9, *S. O. 46, A. G. O., Washington, D. C.*, February 28, 1891.

By direction of the Secretary of War, the extension of the leave of absence granted WILLIAM B. DAVIS, *Captain and Assistant Surgeon*, in Special Orders No. 22, February 5, 1891, Division of the Atlantic, is further extended one month.—Par. 7, *S. O. 21, A. G. O., Washington, D. C.*, February 28, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 7, 1891.

RUTH, M. L., *Surgeon.*—Granted one month's sick-leave.

EVANS, S. G., *Assistant Surgeon.*—Detached from the Naval Academy, and ordered to the "Monongahela."

PRICE, A. F., *Surgeon.*—Ordered to the U. S. S. "Monongahela."

HARRIS, H. N. T., *Assistant Surgeon.*—Ordered for examination preliminary to promotion.

PICKERELL, GEORGE MCC., *Assistant Surgeon.*—Ordered for examination preliminary to promotion.

AUZAL, ERNEST W., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Lancaster."

NORTH, JOSEPH H., Jr., *Assistant Surgeon.*—Ordered to the U. S. S. "Lancaster."

GAINES, JAMES H., *Surgeon.*—Ordered before the Retiring Board, March 12th.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FIVE WEEKS ENDING FEBRUARY 28, 1891.

PETTUS, W. J., *Passed Assistant Surgeon.*—Relieved from special duty as Inspector of Immigrants at the Port of Boston. Ordered to the Marine Hospital, Boston, February 10, 1891.

PERRY, T. B., *Assistant Surgeon.*—Granted leave of absence for thirty days, February 20, 1891.

GOODWIN, H. T., *Assistant Surgeon.*—Relieved from duty at Cincinnati, Ohio. Ordered to Marine Hospital, New York, February 9, 1891.

COFER, S. E., *Assistant Surgeon.*—Detailed for special duty as Inspector of Immigrants, Port of Boston, February 10, 1891.

EAGER, J. M., *Assistant Surgeon.*—Assigned to temporary duty at Cincinnati, Ohio, February 20, 1891.

APPOINTMENT.

EAGER, JOHN M., of Pennsylvania.—Commissioned as Assistant Surgeon by the President, February 16, 1891.

EXTIRPATION OF THE KIDNEY FOR AN ENORMOUS MYXO-SARCOMA IN A CHILD AGED THREE YEARS AND EIGHT MONTHS.

BY A. V. L. BROKAW, M.D.,
DEMONSTRATOR OF ANATOMY AND OPERATIVE SURGERY IN THE MISSOURI MEDICAL COLLEGE; JUNIOR SURGEON TO ST. JOHN'S HOSPITAL, ETC.

AMONG the rare occurrences in operative surgery is the successful treatment of malignant renal diseases in children. This is shown by the alarming mortality in these cases of 44.9 per cent. due to the operation. The removal of tumors from the kidney in children is an operation of recent date; for it has only been a very short time since surgeons would not attempt operative interference. Fischer[1] tabulated twenty-five such cases, with a mortality of 48 per cent.

Czerney,[2] Schede and Roberts have also contributed to the cases on record. The literature up to date, including a case lately reported by Dohrn (Königsberg), contains twenty-nine cases, bearing the above gloomy figures of 44.9 per cent. mortality.

In view of these facts the case to be presented, and especially the technique of the operation, will contain points of no little interest to the surgeon.

The patient, a boy, aged three years and eight months, came under my observation on November 14, 1890. According to the statements of the parents the child had been complaining since June, 1890, of pain and general discomfort in the right side of the abdomen. Just beneath the free margins of the ribs there appeared a swelling or protrusion which led an irregular physician in charge of the case to the diagnosis of "hypertrophy of the liver." Until two weeks before I was consulted the boy had been engaged in his childish pastimes, playing as usual and giving no evidence of the frightful process which was going on within.

The unmistakable growth, which was now diagnosed, appeared so extensive that I expressed an unfavorable view of operative interference. The tumor filled entirely the lumbar and half of the umbilical region, extending from one and a half inches above the anterior superior spine of the ilium to the free margin of the liver, and on the right side it extended nearly to the middle of the left rectus muscle. It gave a peculiar elastic, almost fluctuating, sensation when palpated; so marked, in fact, that the idea of a cystic growth was entertained by a consultant. The thoracic viscera were normal and nothing of pathological import was revealed by a careful urinary analysis.

In the face of these facts and the tender age of the child the case appeared, to say the least, formidable; so that taking into consideration the general circumstances of the case, and having in mind the great mortality from the operation, I expressed a reluctance to interfere. The father, however, insisted, and accordingly preparations were made for operating on the following day.

Under chloroform I made an incision six inches in length, extending from the margins of the quadratus lumborum muscle to midway between the last rib and the crest of the ilium. A few strokes of the knife brought the tumor to view. It presented a peculiar grayish color, with large venous trunks radiating over its surface. An attempt was made to separate the tumor from the ascending colon without entering the peritoneal cavity; failing in this, however, an opening some five inches in length was torn in the peritoneum. Firm adhesions had formed in almost every direction around the tumor, which made the enucleation of the growth exceedingly difficult. In separating some of the adhesions the capsule of the tumor was ruptured, and with a sudden gush the larger portion of the soft jelly-like mass escaped into the abdomen. Time was an all-important factor, and without stopping to meet this accident I hastily separated the adhesions binding the growth to the hepatic flexure of the colon and liver. I quickly formed a pedicle of the blood-vessels and ureter, and then passed an aneurismal needle between the latter and the vessels, and tied off the kidney with a modified Staffordshire knot. Having completed this, I introduced my hand into the abdomen and removed all the soft material which had escaped into the cavity. The abdominal cavity was thoroughly flushed out with hot water and carefully searched for any remnants of the jelly-like mass.

The rent in the peritoneum was closed with a continuous catgut suture, and the muscles and skin were approximated with silk sutures. A tampon of iodoform gauze was inserted into the deeper part of the wound, and a heavy dressing of bichloride gauze

[1] Deutsche Zeitschrift für Chirurgie, 1889, Bd xxix.
[2] Arch. für Kinderheilk., 1890.

and absorbent cotton was applied and retained in position with a broad bandage.

The shock of the operation was severe and he did not rally completely for four or five hours. The amount of blood lost during the operation was of necessity considerable. Every effort was made to complete the work in the shortest space of time, the entire operation lasting but twenty-three minutes. Fortunately the wound healed by first intention, and the convalescence of the little patient was rapid.

After removal of the gauze tampon on the third day no further provision for drainage was deemed necessary, and a permanent dressing was placed over the wound. This was not removed for two weeks. Three weeks only had passed after the operation, when the boy resumed play indoors, and in less than a month he was in a fair state of health and able to be out of doors. For a period of two months he was free from all symptoms of the original trouble; but within the past ten days he has manifested some peculiar gastric disturbances which I fear indicates a metastasis. As might be supposed, the child's condition before the operation was deplorable. But after the removal of the offending growth he improved in every respect. His appetite was excellent and his strength seemed fully restored.

February 3d. On the night of January 26th the child was taken quite ill and gradually sank, dying February 2d. A metastasis to the liver and stomach had taken place and the tumor almost equalled in size the original growth in the extirpated kidney.

TREATMENT OF PLACENTA PRÆVIA.

By H. H. VINKE,
OF ST CHARLES, MISSOURI.

My excuse for venturing any opinions on a subject upon which so much has already been said by eminent writers is its extreme importance, and though I can offer nothing particularly new, I will attempt to present in a manner as brief as possible the most reliable means at our disposal to treat one of the most dangerous complications of labor. In text-books, as a rule, heroic measures are recommended and immediate interference is advised in cases where the hæmorrhage is at all alarming and the child is supposed to have arrived at a viable age. The object of this communication is to plead for more conservative treatment. The fact that forcible dilatation of the os and the turning of the child are operations in themselves so grave that they may cause the death of both mother and child, and that even then the entire placenta may be expelled before the birth of the child without the loss of any serious amount of blood, would seem to justify this plea. This was forcibly impressed upon me about a year ago, when I was called upon to treat a case of this nature, and though the child was born dead, the mother lost no more blood than during a normal labor.

Unfortunately such favorable terminations are the exception, and, as a rule, in cases of abnormal attachment of the placenta, the skilful, intelligent, and timely assistance of the accoucheur is imperatively demanded. At any period of gestation hæmorrhage may set in, and it is generally the first symptom pointing to an abnormal attachment of the placenta. At times the loss of blood is only small and is spontaneously arrested; at other times the amount is so large and so sudden as to at once place the life of patient in jeopardy. It is usually held that in these cases, particularly in advanced pregnancy, it is best and safest to at once induce labor; but my limited experience would seem to teach that, as a rule, hæmorrhage can be arrested by proper tamponing, and that it is safer to wait for labor to set in spontaneously than to induce it artificially.

When called upon to treat hæmorrhage the result of abnormal attachment of the placenta, I would content myself with arresting the hæmorrhage until labor sets in spontaneously. After labor has set in, I would rupture the membranes as soon as possible. In partial placenta prævia this can be done during the earlier part of labor; in the central form it will probably be impossible until labor is well advanced and the os well dilated. It will be found, however, that at the very beginning of labor the flow of blood is most alarming, and that as the os becomes more and more dilated, the flow of blood becomes more and more diminished. If, however, after the complete dilatation of the os the patient should still continue to lose blood in considerable quantity, and her condition be such as to imperatively demand immediate delivery, turning may now be resorted to, and can, as a rule, be readily accomplished if the attendant will take time and first make out carefully the relation of the child to the mother. Beside insisting upon absolute rest and treating general symptoms as they may arise, it would seem to me that we may safely rely upon the tampon for almost completely arresting all hæmorrhage.

The use of antiseptic material for tamponing renders it unnecessary to replace the tampon every five or six hours, as advised in our text-books. The frequent introduction of a tampon into the vagina is a source of great annoyance to the patient, and has a tendency to render the vagina very sore and painful. Antiseptic tampons can be safely left in place for twenty-four or forty-eight hours.

The vagina cannot be successfully plugged without the use of either Sims's or Simon's speculum. As to

the material to be used for a tampon, I have found corrosive sublimate gauze most useful. It has always seemed to me that failure of plugging is usually owing to the fact that the plug employed is too small, for it is only by packing the gauze well around the os and by filling the whole vagina with the same material that we can expect to control the hæmorrhage successfully.

It will frequently be found that these tampons excite labor pains, thereby assisting in bringing labor to a rapid and successful close. While labor is in progress the plug may be expelled during a pain, and if labor has not sufficiently advanced, it may become necessary to again and again plug the vagina until the finger can reach beyond the margin of the placenta and rupture the membranes. As soon as this is done, labor will rapidly come to a close; the presenting part will insinuate itself in the os, and in doing so will arrest the hæmorrhage.

To reiterate, it would seem that it is not judicious, as a rule, to forcibly induce labor, but that it is safer to wait for labor to set in spontaneously. All antepartum hæmorrhages can be completely controlled, as a rule, by properly plugging the vagina. These antiseptic plugs may be safely left in place for twenty-four or forty-eight hours, and can be renewed whenever required. After labor has set in, the membranes should be punctured as soon as practicable.

CAN HYPERMETROPIA BE HEALTHFULLY OUTGROWN?[1]

BY B. ALEX. RANDALL, M.D.,
PROFESSOR OF OTOLOGY IN THE UNIVERSITY OF PENNSYLVANIA AND THE PHILADELPHIA POLYCLINIC; OPHTHALMIC AND AURAL SURGEON TO THE CHILDREN'S HOSPITAL, ETC.

IN the study of refraction and its anomalies it might be claimed that little advance has been made, in spite of the immense amount of work that has been done in this direction, since the era inaugurated by the treatise of Donders. That treatise marks a stage which some of the ophthalmologists of to-day have not yet attained; and while progress, real and considerable, has been achieved at many points, there are some in the profession who seem to close their eyes to this, and persist in holding views no longer sustained by the facts. One of the views thus adhered to is that of the general prevalence of emmetropia—an assumption that has its comfortable side, and its long list of authoritative upholders, yet is surely in conflict with the experience of every careful student. We have outlived Jaeger's teaching that infants are born myopic; and have quite generally accepted the showing of all later investigators that infants are almost without exception hypermetropic. Yet, the investigations which show hypermetropia in the majority of school children have met less acceptance, and studies which even *define* emmetropia as being "normal vision," are offered as sufficient to prove the contrary, while the known prevalence of hypermetropia after loss of the accommodation is explained by a theory of "*hypermetropia acquisita*," backed by the great name of Donders.

Much as we have received from that master, which seems destined to remain an enduring monument of his labor and insight, there is danger that admiration may go much too far in upholding hypotheses which he framed to fill the wonderfully few gaps in his knowledge of this difficult subject. Surely his pupils have ill learned the lessons which he taught, if they insist upon the points which he himself held only tentatively, and try to maintain his unsupported dicta in the face of adverse evidence. It is as a most admiring follower of Donders that I wish to question some of the views which to-day pass current largely upon the authority of his name, for I believe them to be erroneous, and wish that his sanction of them should be forgotten. In a previous paper[1] I endeavored to show that he did not hold the view generally adduced from his much misused paragraph as to "tone of accommodation," which undermines his formal definition of emmetropia; and in the present instance I would call attention to another misunderstood passage of his treatise—that on the frequency of the occurrence of myopia (p. 341). He here gives a diagram, based principally on his case-books, to indicate the relative frequency of the various degrees of refraction error in the Dutch population—a diagram which might be understood to indicate that emmetropia is about as common as the lowest grades of myopia or hypermetropia, were it not expressly stated that the lines representing these are only one-tenth of their proper length. In fact, then, he distinctly states that emmetropia is found in less than 2.5 per cent. of the population, although he had made outside observations in order to correct the possibly erroneous indications obtained from eye cases only. Myopia of $\frac{1}{96}$, or less, he reckons as occurring in 37.5 per cent. of the population, the corresponding grade of hypermetropia in 45 per cent.; and it is only by counting these as practically emmetropic that 85 per cent. of emmetropia is obtained. Donders is far from teaching, therefore, that emmetropia predominates; and although he indicates that he had a larger proportion of myopes than of hypermetropes in his experience, and that the medium grades of hypermetropia are not very common, his results are not extremely different from those which I would urge as correct.

[1] Read at the Twenty-sixth Annual Meeting of the American Ophthalmological Society, July 16, 1890.

[1] Read before the Ophthalmic Section of the American Medical Association, May, 1890. Journ. Am. Med. Assoc., Jan. 1891.

In previous publications[1] I have brought together as completely as possible all the investigations to date of the refraction of the eyes of school-children and others, in the endeavor to learn what is the prevailing refraction of the human eye: with the result of showing a decided preponderance of hypermetropia, a small percentage of emmetropia, and a varying proportion of myopia, depending upon the age, class, and education of those examined. Divergent as were the results which had been obtained by various investigators, the consensus of them all gave distinct pointings, and critical study of the methods used in each examination rarely failed to give full explanation for the deviations from the average result.

These results have hardly received wide acceptance, reiterated as they have been by many of the best students of the subject, and they have been given little of their due importance in practice. Theoretically, it is generally conceded that all children, as well as the new-born, are usually hypermetropic, yet it is constantly being re-discovered as a new fact, peculiar to some special group of individuals, and is employed as a positive proof of any theory that needs support. The frequency and the importance of refraction errors (in many cases) are incontestable, and will be little weakened by such misuse of the facts; yet it does not speak well for the judgment of the profession that men are so prone to ignore or to try to explain away these teachings, except when they have special use to make of them.

Most of the investigations referred to here were undertaken in order to throw light upon the etiology of myopia. They showed a disquieting rise in the percentage of this defect from the lower to the higher classes in schools, and of course there were enthusiasts to raise a hue and cry, thunder at the overburdening of the scholars, and draw all sorts of wide-reaching conclusions from ill-determined and insufficient data. Reaction was inevitable, and Donders, whose dictum, "a myopic eye is a diseased eye," had been the war-cry of the crusade against myopia, led the recoil toward the view that myopia is a mere revolutionary adjustment of the eye to its environment, and wrote: "Were it in my power to eradicate all myopia from the world, I would not do it." To-day Cohn and others are contending that myopia is a curse of civilization, to be fought by the "school physician," and his hygienic dictatorship; while Stilling and others regard all except the high grades with equanimity—rather proud of its prevalence in Germany, as a proof of the national evolution into special fitness for the highest civilization. Hypermetropia, it is held, is a condition of under-development common to the brute, the infant, the savage, and the idiot, and is put off with other childish things when manhood is attained. This view, with various modifications and corollaries, is quite widely held, having gained ground since it was advanced, especially by Landolt and Dor, some twelve years ago, and it is to it particularly that I wish to draw attention.

The short hypermetropic eyeball has always been regarded as in a condition of under-development; yet it is a newer and less prevalent view that hypermetropia is merely a *stage* of incompleteness. It is quite natural that further growth toward the emmetropic standard should be expected of this as of other infantile organs, and this *à priori* view gains strength from the fact that, as Jaeger has shown, the infantile eye lacks about six mm. of its adult axial length. Add to this view the fact that infants are almost invariably hypermetropic, often to a considerable degree, while adults are assumed to be emmetropic, and the position seems hardly open to attack. Further, it has been claimed by some investigators that they have demonstrated this progressive decrease of the juvenile hypermetropia, as when Germann found the average hypermetropia to be 5.3 D. in the first month of life, 3.3 D. in the second month, and 2.3 D. in the earlier years. Hansen also found an average hypermetropia of 1.75 D. in the tenth year, declining to 0.75 D. at the fifteenth.

Decrease in the refraction of eyes, especially of children and young adults, has been frequently observed, not only in cases of progressive myopia, but in a considerable series of hypermetropic eyes, as has been recorded by Drs. Risley, Norris, and others. Yet, I fail to find in any of the instances any reason to believe that such a change was brought about by a physiological growth. All have presented clear evidences of pathological processes, and the combating of these by the usual therapeutic measures for reducing intra-ocular inflammation was followed by a relief of the distressing symptoms usually present, and by a cessation of the change in the refraction. Many of the cases alluded to I have had the privilege of studying, and as others have occurred in my own practice, I have had some experience with the pathological form of the change. But of an increase which could be regarded as healthy, I have met no single instance among many thousand cases.

In a lecture recently published, Macnamara urges that young hypermetropes, even those with absolute hypermetropia, should not be given their correcting glasses, or even under-correcting lenses, for more than the absolutely necessary use at near work, much less for constant wear; and claims that the normal development of the eye, whereby the hypermetropia

[1] American Journal of the Medical Sciences, July, 1885; Transactions of the Seventh International Ophthalmological Congress, 1888.

would be outgrown, might thus be interfered with, and the defect rendered permanent. The same idea had previously occurred to me, and led me to give under-correcting glasses to cases of high hypermetropia, for I had seen enough cases of this kind in which five years had wrought no change in the refraction to feel confident that *under the full-correcting glasses* hypermetropia did not tend to decrease. I have since found occasion in some of these instances to increase the convex lens, because the patient gave evidence of requiring fuller correction. In no case have I observed decrease in the hypermetropia, and I am now wholly sceptical as to its occurrence, and shall rarely repeat the experiment.

Inclining to reject this view, then, as being unsupported by any facts derived from my own experience, and conflicting with much that I have observed, it remains to be seen whether it is tenable in the light of the studies of the eyes of the children in the schools. Some supporting results have been already cited. Are they corroborated by the general result or by other reliable investigations? My answer must be in the negative, since the small decline observed in the hypermetropia seems quite fully accounted for by the causes of pathological distention, which are known to be at work during childhood.

The study of the average refraction of children will be best begun by examining the findings as to the eyes of newborn infants, as to which five investigations, those of Ulrich, Bjerrum, Schleich, Horstmann, and Germann, are available. (See Table I.) Germann found 19.11 per cent. of infants to have hypermetropia = 9 to 12, and 50 per cent. hypermetropia = 4.5 to 8 D. in the first month; while later there were none over 8, and only 14 = 24 per cent. over 4 D. In his young children he found three eyes with hypermetropia = 7, 8, and 9 D., respectively; 2 = 6, 2 = 5.5, and 7 = 4.5: only 14 = 12 per cent. over 4 D. Yet Schleich found but 1 in 300 as high as 8, and $\frac{1}{31}$ = 7 D.; and none of the other investigators met any such grades. The high average hypermetropia shown by the table rests, therefore, upon the work of Germann and Schleich upon 520 eyes; while among 414 eyes examined by others the average was only 2.6 D.; and among 756 eyes, as to which the grade is not specifically noted, the lower grades seem to have predominated, *e. g.*, 2 to 2.5 among Koenigstein's 562 cases. Horstmann's very careful work was done after the first week of life, and it is highly probable that just as he saw practically nothing of the retinal extravasations frequently met in the first week, so, too, he did not see the accompanying swollen disc, the temporary prominence of which was probably measured by the others. Thus only can we understand the remarkable decrease of 2 D. in the average hypermetropia from the first to the second month of life (from 5.37 to 3.30) found by Germann. It seems probable that the average hypermetropia about birth is rather below than above 3 D.

Passing on to the results in young children not yet of school age (Germann's were from one and

Some caution is probably necessary in accepting as general the results of several of the investigations, even though they give evidence of rather special accuracy. Their discordance with other results, apparently as carefully obtained, brings their weight somewhat into question, and indicates that, though perfectly accurate, they may be accidental. Thus

one-half to ten years, but unschooled), the few available records are as in Table II.

Only Horstmann's earlier study differs from the rather remarkable coincidence of the other figures, with which, too, a further study of his seems to have been in close accord. We may, therefore, accept this average as a little above 2 D., as shown.

Turning now to the results in the schools, and using, as before, every group of figures which affords the requisite data as to age and grade of refraction, we obtain from the studies of Callan, Dennett (Hyde Park and Nantucket), Howe, Emmert, Risley, Collard, Van Anrooy, Hansen, and myself the results shown in Table III.

An almost unvarying grade of hypermetropia would seem to be the average during this period, for the utmost variation is less than 5 D., and even this may be regarded as perhaps accidental. Much of the variation is due to Hansen's figures, his 412 eyes with an average hypermetropia = 1.75 at ten years, and 242 eyes with only hypermetropia = 0.75 at fourteen, change the averages at those ages from 1.20 and 1.22 to 1.48 and 1.09. A very slight downward tendency appears when we sum up the results for each five years of life, the average grade being 1.31 for the second period, 1.24 for the third, and 1.13 for the fourth; that for the whole 7530 eyes being 1.24 D. Data are lacking from which to endeavor to compute the average in early adult life—Seggel's examination of recruits in the Munich garrison stands almost alone. He found with the test-glasses an average hypermetropia = 0.40 in more than 3000 eyes.

Such, then, is the evidence bearing upon our question which I am able to find in the literature; figures which, taken at their face value as all of equal weight, go but a short way toward proving any notable decline in the hypermetropia with the growth of the individual; yet it requires no deep study of the investigations furnishing these results to convince one that they are far from being all of equal value. Further, there are many studies which do not furnish their results in shape for our tabulation, yet are very distinct in their pointings, and probably more trustworthy than some of those used. The strongest case possible has been made for the view that hypermetropia is outgrown, and while I do not propose to undertake the invidious task of showing the flaws in the studies cited, I will point out some of the investigations which seem to be of most weight, and offsetting more or less the results above given.

In his study at Schreiberhau under atropine, Cohn found the average hypermetropia of 295 eyes of children, six to thirteen years of age, to be 1.20 D., with no relation of the grade to the age. Callan, among 346 eyes of negro pupils, found the average grade 1.23 D. present in all ages from six to nineteen years with only accidental variations. Schadow, among the 240 hypermetropic eyes which he studied in Borchum, found an average of 1 D. at seven to eight, 1.7 at nine to ten, and intermediate grades at the other ages (six to fourteen years). Conrad found an average hypermetropia of about 1.25 among his younger pupils (aged six years), with rather higher grades in the next years. Emmert, among his 3279 hypermetropic eyes found an average of 1.16 in the five to ten, 1.38 in the eleven to fifteen, and 1.31 in the sixteen to twenty, the general average being 1.31 D.

Numerous other points could readily be cited in support of the conclusion which I have drawn from my study, that there is a very insignificant decline, if any, in the grade of hypermetropia during school life, and when the occurrence of quite frequent pathological progression toward myopia at these ages is taken into consideration, the surprise must be that the decline is so small. There is some evidence that higher averages of hypermetropia are to be found before the school period than later, but a number of considerations explain away, to a great extent, this apparent showing. All of the reliable measurements of refraction of the very young have been made under a mydriatic; and while far from believing that this introduces any element of error, I must hold them as not strictly comparable with the results obtained without a mydriatic. The grades of hypermetropia met in mydriatic work are in no need of being scaled down, for the reason sometimes urged that the mydriatic must be discounted because it gives a fictitious hypermetropia. Properly used, the mydriatic can only have increased the accuracy of the results. But to make them really comparable, the averages found without a mydriatic most certainly need to be scaled up—are subject to a considerable increment to represent the latent hypermetropia which escaped measurement. The use of the ophthalmoscope, which was all too rare in the investigations cited, can do something toward this end; but only an ultra-enthusiastic ophthalmoscopist could close his eyes to its very numerous shortcomings, and believe that its results could not be decidedly improved upon. One of the investigators quoted above questions his results on the ground that with the ophthalmoscope he was measuring hypermetropia of his own instead of that of the patient; yet a comparison of his objective results show that while he *uncovered* hypermetropia in thirty-five eyes which had no manifest hypermetropia, he failed to see the hypermetropia with the ophthalmoscope in 105 eyes which had already revealed it with the test-glasses. Such results are common among the younger pupils; but my own study of medical students shows that the same thing holds among the elder. Not only did the opthalmoscopic measurement raise the percentage of hypermetropic eyes from 26 per cent. to 72 per cent., but it also increased the average hypermetropia from 0.57 to 0.85 D. So, too, Cohn found among his 299 atropized eyes 98 per cent. of hypermetropia, and an average of 1.20 D., where, without the mydri-

atic, there had been but 82 per cent. hypermetropia, with an average of 0.75 D. Reasons have already been given for the belief that the average hypermetropia at birth is below 3 D., and we here see that the 1.25 of school life should be considered to represent a real average of about 2 D.; so I believe we shall not go far astray if we accept a dioptre and a half as representing the extreme limit of the real average decline in the refraction from birth to adult life.

Such a change in the refraction is far from unimportant, and would abundantly serve the purpose of those who claim that hypermetropia is outgrown, could they adduce any evidence that it is due to physiological growth. In the utter absence of any such evidence, so far as I am aware, and with the all too probable explanation that the pathological progress toward myopia is alone responsible for the change in the many, as it undoubtedly is in the few, my position of scepticism as to any normal decrease in hypermetropia seems fully justified. The burden of proof certainly rests upon those who wish to uphold such a view.

Two arguments deserve notice in closing. In twenty sections of the eyes of newborn infants, Von Jaeger found the average axial length to be 17.5 mm. as against 23.4 mm. in as many adult eyeballs. Yet, these were by no means the shallow eye-balls of high hypermetropia, for in almost every instance the axis was the greatest diameter of the globe, the vertical average being but 16.4 mm., and the horizontal 17.2 mm. While such an axial length in an adult eye might correspond with a hypermetropia of some 35 D., it must not be forgotten that the infantile lens has its full adult thickness, although its diameter is only 6.3 mm. instead of nearly 9 mm., and consequently that its curvatures are such as probably, even in its comparatively homogeneous condition, fully compensate for the proximity of the retina. Whether it has a proportionately forward position,[1] as indicated by the shallow anterior chamber, need not be discussed until some evidence is brought forward to show that the other compensation would not be complete. If it can nearly compensate for so high a grade of axial shortening, it will be difficult to prove that it is not fully competent, however wonderful it may seem, that the eye-ball should undergo such changes in its dimensions without alteration of its refraction.

The other point which deserves a passing notice is the view that the tendency toward myopia is an evolutionary adjustment of the eye-ball for the demands of near-work to which it is subjected in modern civilized communities. Until proof is adduced to show that myopia is actually inherited, such a view has no claim to be treated as even a scientific hypothesis; and its demonstration is almost impossible. It has been repeatedly seen that scoliosis and myopia were developed together by faulty positions of school-children, especially in writing, and whoever undertakes to champion the evolutionary meaning and value of the one may well be challenged to uphold the same view as to the other.

[1] It is quite probable that many of the cases of myopia found at birth, some of which have been observed to decrease in the following months, have been due to a forward displacement or subluxation of the lens.

A CASE OF TREPHINING FOR DEPRESSED FRACTURE AND ENDOCRANIAL HÆMORRHAGE.[1]

BY SPENCE REDMAN, M.D.,
OF PLATTE CITY, MO.

ON November 1, 1890, E. M., aged three years, while playing in the pasture was kicked upon the forehead by an unshod mule. He climbed over the fence and ran to the house, about fifty yards distant.

I saw him one and one-half hours after the accident. He was unconscious, although I learned from his parents that he was able to speak for twenty or thirty minutes after returning to the house. Both pupils were widely dilated and would not respond to light. The pulse was rapid (120 per minute), regular, but wiry. His respiration was 30 and labored, soon becoming stertorous. His axillary temperature was $99\frac{3}{5}°$. He vomited every few minutes and passed his urine involuntarily. When I first saw him the muscles of the right arm and leg twitched incessantly. These movements are best described as rhythmic clonic spasms, and were most marked in the muscles of the forearm, and increased in severity up to the time of the operation. He held his head slightly to the left side. A horse-shoe-shaped scalp wound four inches long was discovered on the right side, the centre being immediately over and one-quarter of an inch above the right eye, the two ends extending upward.

The scalp was well shaved and the wound thoroughly cleansed with bichloride solution. The flap was then raised and a fracture of the frontal bone one and a half inches long was found. It was situated midway on a line drawn from the glabella to the superior stephanion. Its direction was transverse and half an inch of the central portion was depressed about one-fourth of an inch. Fearing that the internal table was more extensively fractured, and being convinced that a clot had formed from a rupture of one of the anterior branches of the middle meningeal artery, I trephined three hours after the injury, being assisted by Drs. Baldwin and Coffey. A hypodermic injection of morphine and atropine was given and the patient placed under the influence of chloroform. The instruments were sterilized by heat, placed in a carbolized solution, and a 1-to-2000 corrosive sublimate solution was provided for the sponges. A button, including the depressed portion of the external table, was removed

[1] Read before the Medical Society of the Missouri Valley, December, 1890.

with a three-quarter-inch Galt trephine. The internal table was found to be extensively fractured—a fissure at right angles to the transverse fracture, which also involved the internal table, extending to within a short distance of the orbit. The internal table on the outer side of this was depressed and considerable trouble was experienced in elevating it. A clot about three inches in diameter, the greater portion of which was below and back of the trephine opening, was removed with the finger and spoon. The wound was then thoroughly washed out with bichloride solution and the dura found considerably contused and containing a few very small punctures; it did not bulge in the opening and was not incised. A few strands of catgut were placed in the wound to effect drainage, and the scalp closed with continuous catgut and four interrupted silk sutures, except one-half inch of the lower portion.

The usual antiseptic dressings were applied and held in place by adhesive plaster.

Immediately upon recovery from the chloroform the patient was able to talk, and there were no more muscular tremors. Occasional vomiting, however, continued for thirty-six hours. The patient was put upon milk diet and one or two doses of morphine were given daily to insure quiet. The wound was dressed fourteen hours after the operation, at which time the catgut drain was removed, as there was not sufficient discharge to warrant its retention. At this time the pupils were but slightly dilated and responded to light; pulse was 90, respiration 20, temperature 99°, and patient complained of slight pain in the head.

The wound healed by first intention, save the portion left open for drainage, which had closed by granulation at the end of ten days. At the present time, one and one-half months after operation, patient is in every respect well, and the button-hole partially filled with fibrous tissue.

I regard the foregoing case as interesting and worthy of consideration, not only because the rapid subsidence of serious brain symptoms adds another link to the now long chain of cases that make early operative interference imperative when there is compression of brain tissue, be it from depressed fracture or hæmorrhage, but also because it, in the main, bears out the statement that centres of special sense and voluntary motion exist and can be pretty accurately mapped out upon the skull. In connection with this it must be remembered that the relations between the brain and skull differ at different ages. Owing to the imperfect development of the frontal lobes in the child, as Hamy has pointed out, the fissure of Rolando lies much farther forward and is more oblique (52°) in its direction. Symington has also told us that the Sylvian fissure is much farther above the squamo-parietal suture in the child than in the adult—from one-half to one inch above. The adult relation of these parts is probably not attained until the ninth or tenth year.

It is owing to this fact, in the case I have just recorded, in which the injury was well forward, that symptoms showing compression of centres as far back as those for the movement of the opposite leg were present.

Aphasia in this case must have been due to pressure on the right inferior frontal convolution, and while we generally expect aphasia to be the result of injury to the left hemisphere, yet several cases have been recorded in which it followed disease of the right lobe and of lesion of the left in which it was absent.

As a general rule, the seat of speech may be said to depend on the person being either right or left-brained. Most persons are right-handed and left-brained; hence, aphasia is generally due to lesion of the left hemisphere. My case departs from this rule, however, in that the boy is right-handed.

According to Kuhn, the most constant, and by far most valuable, symptom of hæmorrhage from the middle meningeal artery is a certain period of time between the accident and unconsciousness. This period is longer or shorter in accordance with the size of the artery, and is due to the fact that a certain length of time is necessary for enough blood to accumulate to produce unconsciousness by pressure. In the case I have described it was between twenty and thirty minutes.

While there was no hemiplegia (the next most valuable sign of hæmorrhage) in the case, I am convinced that the muscular tremors were warnings, and that the arm and leg would shortly have become paralyzed. The rapid stertorous breathing, frequent pulse, dilated immobile pupils, and elevated temperature all pointed to hæmorrhage, but they had not the diagnostic importance of the lapse of time before unconsciousness and hemiplegia.

I shall not burden the reader with statistics showing the importance of operative treatment, since I feel sure all will agree that when there is reasonable ground to believe that the middle meningeal or any of its branches has been injured, the skull should be opened. The position for the opening must be determined by the symptoms and not the location of the injury, since the artery is not infrequently ruptured on the opposite side to the skull wound. Failure to recognize this fact has caused many lives to be lost. Had the aphasia in my case continued after the opening on the right side had been made, I should have felt justified in trephining over the left inferior frontal lobe, for we sometimes have rupture of both middle meningeal arteries from the same blow.

Two things are, in my opinion, imperative in all operative procedures upon the brain, viz.: thorough drainage and antisepsis. It is chiefly to these that I attribute the success of the operation.

The advisability of re-implanting the trephine button is still a mooted question. As even large

portions of the skull can be removed and the opening left to heal over with fibrous tissue, the advantages to be gained by implantation of the button or transplantation of bone from an animal can hardly repay the delay in healing. As most operations are performed for pressure, and implantation causes a flattening of the skull surface, it would seem an unwise procedure. For these reasons I have never replaced it; however, should it be desired to close the opening with osseous tissue, McEwan's plan is preferable to replacing the entire button, as by the latter plan there is danger of necrosis.

PELVIMETRY FOR THE GENERAL PRACTITIONER.

BY J. WHITRIDGE WILLIAMS, M.D.,
OF BALTIMORE.

THE subject of pelvimetry, important as it is, is usually totally neglected in most of our medical schools, and any knowledge that the practitioner has of the subject he has been obliged to glean for himself. And he receives but little encouragement to pursue its study when he reads Lusk's statement that in our native American women abnormal pelves are rare, and hears physicians of experience state that in thousands of cases they have never met with a single deformed pelvis; though they will willingly admit that they have performed craniotomy on numerous occasions.

Of course, these statements apply only to those marked cases of deformity which no one could fail to recognize after a most casual examination.

While the extreme degrees of deformity may not be as frequent here as in Europe, still they do occur, and that often enough for us all to be on the lookout for them.

These, however, constitute only a small portion of contracted pelves; and through our neglect of pelvic measurement we lose sight of the far more frequent cases of moderate contraction, in which there is no absolute bony resistance to the passage of the child, but still resistance enough to make the labor most difficult and dangerous, or to cause such abnormalities in the position or presentation of the fœtus that its delivery may become almost impossible. Michaelis called attention to this fact years ago, and stated that the evil effects of a moderately contracted pelvis were due, not so much directly to the bony resistance as to its effects upon the position and presentation of the child, and showed that transverse presentations occurred from four to five times more often, and prolapse of the cord alongside of the presenting head ten times more often, in contracted than in normal pelves.

In the German institutions, where pelvic measurements are an integral part of the conduct of each labor case, the frequency of contracted pelves—that is, pelves with a conjugata vera of 9½ cm. (3¾ inches) and less, was estimated at from 13 to 14 per cent., the general average being about 14 per cent. or one-seventh of all cases. Admitting that the ratio is somewhat smaller in America, which we cannot positively affirm, for, as far as I know, no one in this country has measured a sufficient number of consecutive cases to obtain reliable estimates, still we cannot afford to attend from one-seventh to one-eighth of our obstetrical cases in the dark and then talk of being skilful and scientific obstetricians.

History.—Our knowledge of contracted pelvis is of comparatively recent date; for to the ancients the condition was unknown and they believed that the child was born by its own efforts, aided by the mobility of all the pelvic bones. It was not until the latter part of the sixteenth century that Aurantius first discovered the contracted pelvis as an anatomical fact. This knowledge was first practically applied by Deventer in the first part of the eighteenth century, who rather accurately described in his book, *A New Light for Midwives*, the principal forms of contracted pelvis, namely, the justo-minor and the flattened, and their effects upon the mechanism of labor, and upon the fœtal head. In the middle of the eighteenth century flourished the great Smellie, who not only recognized the deformity and its effects but was the first to estimate the conjugata vera by measuring manually the conjugata diagonalis, and who recorded cases in which the antero-posterior diameter was not more than one and a half inches. At the end of the century, Baudelocque introduced the external methods of pelvic measurement. He placed the greatest reliance on the external measurements, especially on the external conjugate, which he discovered, and from which he believed he could calculate the conjugata vera with almost absolute exactness, his results only varying a few lines.

These three men laid the foundations for the doctrine of contracted pelvis and pelvimetry; but the honor of placing the subject upon a scientific basis must be ascribed to the famous obstetricians of Kiel, Michaelis and his successor Litzmann. These two measured the pelves of all the cases that came under their care and were thus able to study the numerical proportion of contracted to normal pelves, thereby showing that contraction was far more frequent than was generally supposed. By accurately observing the mechanism in these cases, they were able to present the subject in so clear and so exhaustive a light that they are still our standard authorities.

Since the time of Michaelis nearly every Continental obstetrician of prominence has devoted considerable time to the subject, without, however, add-

ing much of real importance to the able work of his predecessors, while we, on the other hand, have allowed the subject to fall into almost total neglect.

Aims.—The scientific obstetrician naturally aims to learn all that is possible about the deformity in each case, and will put himself to considerable pains to determine exactly what form of contracted pelvis he has before him, and exactly how and to what extent it is contracted. To do this requires special training and practice, such as the general practitioner is not supposed to possess and which naturally cannot be demanded of him. But he should be expected to recognize the ordinary forms, especially the generally-contracted or justo-minor, and the flattened rhachitic or non-rhachitic pelvis, and should be able not only to recognize the species of deformity, but also approximately to estimate the amount of contraction, especially in the antero-posterior direction. Indeed, on account of the rarity of the other forms of contraction and the extreme difficulty in estimating the other diameters and the varying results of different methods, pelvimetry for the general practitioner resolves itself into recognizing a flattened pelvis and estimating the conjugata vera.

Methods.—Pelvimetry may be divided into external and internal methods; only the latter, however, being capable of giving anything like accurate results. External measurements, except by means of a pelvimeter—and almost any form will do—are utterly worthless, and even those made by means of a pelvimeter point only to the species of the deformity without giving definite information as to its degree.

The principal measurements of the pelvis are three in number:

1. Distantia spinarum—the distance between the anterior superior iliac spines.

2. Distantia cristarum—the distance between the most widely removed points of the iliac crests.

3. Conjugata externa or Baudelocque's diameter—the distance from the depression below the spine of the last lumbar vertebra to the outer surfaces of the symphysis pubis.

Of these, the first two are by far the most important, and they average 26 and 29 cm. (10¼ and 11½ in.) respectively. Mere variations in measurement are not of much importance, so long as the relative proportion between the two remains the same. The careful work of Scheffer some twenty-five years ago showed that the measurements do not justify us in drawing conclusions as to the transverse diametres of the superior strait, as was formerly supposed. Scheffer showed that with equal external measurements, the transverse diameter of the superior strait might show a difference of 3.3 cm. Skutsch has lately verified these results.

While these measurements do not give the much desired transverse diameter, they do give us much valuable information as to the shape of the pelvis. If, for example, in connection with a shortened conjugata vera, both the measurements are markedly decreased, but still retain their relative proportion to each other, we are justified in concluding that we have to deal with a generally-contracted pelvis.

In the rhachitic pelvis, this relation between the spines and crests vanishes, and the distantia spinarum increases at the expense of the distantia cristarum, and may even exceed it, according to the extent to which the iliac bones are flared out. In this latter case, of course, the distantia cristarum cannot be measured in the usual way, and to obtain it we measure the crests at a point from 6 to 7 cm. behind the spine.

In the simple non-rhachitic flattened pelvis we do not get this increase of the distantia spinarum at the expense of the distantia cristarum, for the iliac bones are not flared out, as in the rhachitic form. Baudelocque's diameter may be dispensed with by the practitioner, for the researches of Michaelis, Crede, Schröder, Dohrn, and Skutsch show that it is not nearly so exact as its originator considered it when he stated that, by deducting three inches from it, he obtained the vera with great accuracy in thirty-five cases, his results differing only a line.

This diameter varies in the living from 16 to 23½ cm. (6½ to 9½ ins.), with an average of about 20 or 21 cm. (8 to 8¼ ins.), and to obtain the vera the average amount to be substracted is 9.2 cm. (3½ ins.). But the results vary so much that they cannot be relied upon, and the most that we can say is that a Baudelocque's diameter of less than 16 cm. (6.4 ins.) indicates a contracted pelvis in nearly all cases; less than 18 to 19 cm. (7.2 ins.) in about half the cases; while one of more than 20 to 21 cm. (8 ins.) rarely does so.

Internal methods.—The main point of importance for the general practitioner is the estimation of the conjugata vera, and for its determination many methods have been devised. All the instrumental methods leave much to be desired, for they are always inaccurate or cumbersome, or both. And all methods for measuring the vera directly with the hand are inaccurate, and require for their performance the introduction of the whole hand into the vagina. So, from a practical point of view our chief reliance must be placed upon its estimation from the conjugata diagonalis; that is, the distance from the promontory of the sacrum to the lower margin of the symphysis pubis or the ligamentum arcuatum. To measure the diagonalis, the patient is placed in the dorsal position, and, if in bed, a small pillow is placed under her hips, so that the forearm of the examiner may be depressed to the proper position;

then the index and middle fingers of the left hand, lying one upon the other, are introduced into the vagina, while the remaining fingers are folded against the palm of the hand and serve to press up the perineum. Then the forearm is depressed, and we attempt to reach the sacral promontory; having reached it, we press the ulnar side of the tip of the middle finger against it and retain it in this position, while with the radial side of the same hand we press hard against the lower margin of the symphysis. Then with the finger-nail of the index finger of the right hand we mark the point at which the ligamentum arcuatum touches the measuring finger. The distance from the tip of the middle finger to this mark gives the desired measurement.

This method, by a little practice, gives almost perfectly accurate results—accurate within ¾ mm. Knowing the diagonalis, it is easy to estimate the vera by subtracting from it a given sum—1½ to 2 cm. (three- to four-fifths of an inch). The amount to be subtracted varies under different circumstances, as will be readily understood when we consider our measurements as forming a triangle, of which the conjugata vera and the diagonalis form two sides and the symphysis the base. It will then be readily seen that, with an increase in height of the symphysis, the diagonalis becomes longer in proportion to the vera, and, consequently, the amount to be subtracted is increased. More important than this, however, is the inclination of the symphysis, or the angle it forms with the conjugata vera, for it is readily seen that the greater this angle becomes the longer becomes the diagonalis, and the greater the amount to be deducted to estimate the vera. In general terms, then, the higher and more perpendicular the symphysis, the greater is the amount to be deducted from the diagonalis—ordinarily a little more than 1½ or 1¾ cm. (three-fifths of an inch) in normal and generally-contracted, and 2 cm. (four-fifths of an inch), or a little less, in flattened pelves. This method gives excellent results in lying-in women, and is readily applied in the non-pregnant, especially if multiparous, though it is usually more or less painful.

In non-pregnant women with lax abdominal walls we may employ the so-called external direct method to which Credé and Hardie called attention some years ago, and which Dr. H. A. Kelly is now engaged in studying and testing.

In this method the woman is placed on her back and the abdominal walls gently pressed in by the tips of the fingers of the left hand, till the tip of the middle finger rests over the promontory; then the palmar surface of the hand is brought down upon the symphysis, and with the finger-nail of the right index-finger we mark the point at which the palmar surface crosses the upper surface of the symphysis. This distance, without making any deduction for the thickness of the abdominal walls, represents the conjugata vera with tolerable exactness—within from ½ to 1 cm.—and affords a ready, accurate, and convenient method of measurement for gynecological cases and in the early months of pregnancy.

With these comparatively simple methods at our disposal, I do not consider that we are justified in attempting to conduct a labor case in which there is the slightest possibility of the existence of a contracted pelvis, without measuring the pelvis before proceeding to any action whatsoever.

Indeed, I do not think Fritsch was far wrong when he said "that the physician who would conduct a pathological labor case without mensuration is as inexcusable as he who does not examine the urine when œdema is present"; or Dohrn, who says "that the physician who does not measure the pelvis is comparable to one who diagnoses heart and lung troubles without the aid of auscultation and percussion." Such being the sentiments of these eminent men, it certainly behooves us to receive them with respect and to attempt to follow their advice. To attain results worthy of attention, practice in the art is absolutely necessary, and the only way by which we can attain the requisite skill is by taking every possible opportunity to measure the pelvis. I would therefore advise all who wish to raise their obstetric work above the level of mere midwifery to make it a part of the routine of the first obstetric examination, in every case, to measure the conjugata diagonalis, and from it to estimate the vera; and if it be at all contracted, to take the external measurements, especially the distantia spinarum and cristarum, and from these three measurements attempt to determine the species, and, roughly speaking, the degree of the deformity.

Anyone who will regularly pursue this course will be amazed to find how many moderately-contracted pelves do exist, and will then be able to explain in a rational way many difficult cases of transverse and other presentations, which previously he merely turned or delivered by forceps or craniotomy, and whose abnormal presentation or mechanism he ascribed to some freak of nature rather than to a rational and sufficient cause.

Of course, the practical man may object that what we gain by this is the mere satisfaction of a scientific explanation for hitherto inexplicable facts, and say that it is all well enough for those who pretend to be scientific, but to the practical, every-day man it is useless and not worth the time consumed.

If this were all that we gained from pelvimetry, I contend that it would still be worth the trouble.

But this, while important, is only a small part of what we gain. What we really gain is a correct diagnosis and prognosis, and with these made, treatment follows as a matter of course.

What has been said of the results of pelvimetry in moderate contraction applies far more forcibly to those cases in which more marked contraction exists. For in these cases the results of measurement should be almost our only guide to correct treatment, and should decide for us whether we are to propose Cæsarean section, resort to forceps or version, or allow nature to take its course. With a pelvis of 5½ cm. (2¼ in.) or less, we have an absolute indication for Cæsarean section, for it is attended with as little or less danger to the mother than craniotomy, not to speak of the great gain of saving all the children if resorted to at the proper time. In pelves between 5½ to 7½ cm. (2¼ to 3 in.) we have the relative indication for Cæsarean section—that is, we must offer our patient the choice between it and craniotomy, with the chances in favor of Cæsarean section.

If we measured all our labor cases, would we not more frequently than now discover those requiring abdominal section and promptly institute the proper treatment, instead of waiting till the woman has been in labor many hours, or perhaps days, and, after having exhausted her by numerous attempts at forcing delivery, to propose a capital operation?

It is the neglect of making a correct diagnosis that makes our Cæsarean section statistics so much inferior to those of our German confrères: I am confident that very few of us are willing to admit that it is due to inferior operative skill on our part. It is entirely due to the fact that most of our operations are done on exhausted or practically dying women who naturally cannot be expected to recover; while the Germans determine on the operation before labor sets in, or certainly after the first examination, and do not allow the case to go on blindly.

What has been said about the Cæsarean section applies with equal force to the induction of premature labor; and there can be no possible excuse for allowing a woman—after a difficult craniotomy, for example—to go on to full term again without measuring the pelvis and determining beforehand what should be done. With a pelvis of 8 cm. (3¼ in.) and less, the operation is certainly indicated, and with our present aseptic methods should hardly be more dangerous than a normal labor, and far less so than the craniotomy that is sure to follow if the patient is allowed to go on to term.

I hope these remarks will lead some of us who have hitherto neglected this important part of obstetrics to take up its study; I am sure that, adding the estimation of the diagonalis to the ordinary obstetric examination in each case, they will be surprised to find how many pelves are contracted within moderate limits, and will occasionally find cases contracted to 8 cm. and less.

In these latter cases, unless the physician be a skilful operator and is prepared to perform Cæsarean section under the strictest aseptic precautions, I do not consider that he does his duty to his patient if, when he has made his diagnosis, he does not immediately call in a competent specialist, who shall decide what is to be done. If an operation be decided upon, he will be able to operate upon a patient with the chances in her favor, instead of upon the usual exhausted and dying case.

APPARENT ANTAGONISM BETWEEN THE STREPTOCOCCI OF ERYSIPELAS AND SYPHILIS.

BY ORVILLE HORWITZ, B.S., M.D.,

DEMONSTRATOR OF SURGERY IN JEFFERSON MEDICAL COLLEGE; CHIEF OF THE OUTDOOR SURGICAL DEPARTMENT OF JEFFERSON MEDICAL COLLEGE HOSPITAL; SURGEON TO THE PHILADELPHIA HOSPITAL, ETC.

IT is generally conceded at the present day that syphilis is due to a specific microbe. The cases here recounted would seem to indicate that this disease is due to a pathogenic microörganism, and that the poison produced by the microbe of syphilis is antagonized by that which produces erysipelas:

CASE I.—During the first week of June, 1890, a married man, aged forty years, who stated that he was a clerk, presented himself at the Jefferson Hospital for treatment. He was suffering from phagædenic chancre. The sore appeared ten days after sexual connection and was spreading rapidly. The foreskin was œdematous, with phymosis as a complication. Circumcision was performed, the phagædena treated in the usual manner, and the patient sent to the surgical ward. In the course of a week the inguinal and post-cervical glands began to enlarge, and two weeks later the patient suffered greatly, especially at night, from rheumatic pains in his bones.

One week after admission to the hospital he had a chill, followed by high fever, which lasted thirty-six hours. A superficial pustular eruption, interspersed with a tubercular eruption, soon after appeared on the body, accompanied with alopecia and mucous patches in the mouth.

The early appearance of the pustular eruption proved the case to be one of malignant syphilis.

The usual specific treatment was ordered, and three weeks afterwards he was discharged from the ward and sent to the surgical dispensary, where he presented himself at irregular intervals.

Four months after the appearance of the initial lesion the patient was admitted to the venereal ward of the Philadelphia Hospital completely covered with deep rupial eruptions. He was very weak and anæmic.

The usual specific treatment was employed without very marked improvement. After having been in the hospital about ten days he was seized with a chill, followed by high fever. Erysipelas appeared on the nose and gradually spread over the face and neck. He was at once isolated and the specific treatment was replaced by iron, quinine, and free stimulation.

The patient was in such a wretched condition that both the resident physician and the writer thought recovery impossible; to our great surprise, however, he began to improve, the erysipelas disappeared, and the deep syphilitic sores began to cicatrize, and when he returned to the venereal ward not a single ulcer remained; the deep red scars which covered his body being all that gave evidence of his previous condition.

Specific treatment was once more commenced, and at the end of four weeks he was discharged from the hospital. Mercury in small doses with iodide of potassium is still used, and the patient states that his health is much improved and that he is rapidly gaining in weight.

Case II.—In the early part of July, 1890, the second case presented itself. The patient, according to the popular term was "a man about town." He was suffering from a deep ulcerating gumma of two months standing, situated on the calf of his leg.

The usual treatment was employed. At the end of three weeks there was no improvement, and finding that the patient was suffering from the debilitating effects of the prolonged heat of the season, and was becoming quite weak, he was advised to try the effects of a sojourn at the White Sulphur Springs, and at the same time to continue the prescribed treatment.

At the end of three weeks the writer received an urgent message from the patient to call at his residence. He was found in bed with high fever and suffering from a severe attack of erysipelas of his left leg extending above the knee. While absent from the city he had abandoned all treatment, kept late hours, and indulged in every variety of dissipation. The ulceration was found to be much deeper and to have extended considerably since the last examination. Large doses of iron and quinine with free stimulation were at once prescribed. During convalescence a large slough appeared at the site of the ulceration, and became detached in a few days. The cavity rapidly filled with healthy granulations, and when the erysipelas had disappeared it was found that a scar was all that was left to mark the spot where the gumma had existed. The patient had no anti-syphilitic medicine during his attack of erysipelas.

There has been no occasion for medical treatment since his convalescence, and he is at this time in perfect health.

There is doubtless a marked antagonism between certain classes of specific microbes. Powlanskay has clearly shown that an antagonism exists between the pneumococcus of Friedlander and the bacillus of anthrax, and also between the micrococcus prodigiosus and the streptococcus of erysipelas.

Neumann[1] reports two cases of apparent antagonism between syphilis and erysipelas. His first case was a woman with gumma of the face, who had three attacks of facial erysipelas, followed by the entire disappearance of the syphilitic lesions.

The second was a case of a man, who was attacked with erysipelas six weeks after contracting a chancre. During treatment for the erysipelas, the chancre disappeared. Constitutional symptoms, which were of the mildest type, did not appear until seventy-two days after the attack of erysipelas.

The foregoing cases of syphilis described by the writer, and those reported by Neumann, apparently cured, or at least modified in virulence, by invasions of erysipelas, would seem to indicate that a certain antagonism exists between the microbes of the two diseases, which may have an important bearing on the therapy of the future.

CLINICAL MEMORANDA.

SURGICAL.

Retention of a Foreign Body in the Larynx for Thirty-eight Years.—The following case of a foreign body being retained in the larynx for a long period of time recently came under my notice, and I have thought it of sufficient interest to put on record, especially as the patient's birth, education, and character place the facts beyond reasonable doubt.

C. M. M., white, aged forty-five years, when only seven years old, put an ordinary pin in his mouth while playing, to keep it from another child from whom he had taken it. While running and laughing, it was drawn into the larynx. Sharp pain was felt for a few minutes, but soon passed off, and nothing more was thought of it. These facts were impressed on his memory by the extreme alarm felt at the time, not only by himself but by his family. His health remained good until about fourteen years ago, or twenty-four years after the accident, when his voice became husky and a chronic cough developed, with emaciation and prostration, leading him to believe that he had consumption.

He was treated by several physicians of Augusta, Ga., near which city he then lived, with some benefit, and was assured that his disease was entirely bronchial.

Since then his voice has remained slightly husky, the cough constant and of varying intensity, but on the whole not very annoying, and he has been quite able to attend to his work.

On January 29th, during a fit of violent coughing, a hard, dark object embedded in a mass of mucus, was expelled from the larynx, and on examination proved to be the long-lost and forgotten pin. No blood came up either then or afterward.

Unfortunately, I was not told of this occurrence for some days, and, owing to the man's occupation, more than a week passed before a laryngoscopic examination could be made. This was thoroughly done by Dr. W. Peyre Porcher, with the result here given:

[1] Allg. Wiener med. Zeitung, 1888.

"The patient's throat was found to be susceptible of a very complete inspection. No marks or abrasions were found other than two somewhat inflamed circumscribed areas, situated directly opposite the posterior ends of both ventricles of Morgagni. From the presence of the spots it was inferred that the pin must have lain across the larynx with its two ends embedded in the posterior edge of the two ventricles."

I have been unable to find any record of a foreign body remaining in the air-passages for nearly so long a time. The nearest approach to it is a case quoted by Gross, in which a piece of bone was retained for seventeen years; and a second, in which the retention was for "upwards of eleven years," spontaneous expulsion taking place in both cases. In the first of these cases, it is known that the bone was retained in the lung for a long time, as it produced disease in that organ of so serious a nature as to cause the patient's death.

While it is manifestly impossible for me to prove, in my case, that the pin was in the larynx all these years, the following considerations make it probable:

1. Symptoms of laryngeal irritation for fourteen years, with absence of pulmonary symptoms.

2. The fact that the laryngeal irritation has greatly improved since the removal of the pin.

3. The appearance of the pin shows that it remained in one place for a long time, as it was covered with an incrustation of considerable thickness, its whole diameter being a fraction over one-sixteenth of an inch. Had it migrated through the tissues, it would have been more or less polished, while had it been loose in the trachea, the symptoms would have been so marked as to demand attention and recognition.

Lastly, the discovery of its probable seat in the larynx, and its ejection directly from this organ, would hardly have happened after thirty-eight years of travel.

The pin was almost an inch in length, and a fraction over one-sixteenth of an inch in thickness, the point being slightly bent.

CHARLESTON, S. C.

OPHTHALMOLOGICAL.

Subcutaneous Eyelash.—A woman, aged twenty-eight, presented herself at the eye clinic of the Philadelphia Polyclinic on account of a small projection of the skin of the left upper lid just above the line of the lashes. Vision and refraction were practically normal, and the little prominence on the lid, first noticed a week before, caused no symptoms.

On examination, the fold of skin composing the projection was found to be supported upon the curve of an eyelash imprisoned beneath the epidermis. The lash was readily recognizable by focal illumination through the transparent skin and by the wire-like sensation it imparted to the finger. It was drawn out through a small opening; proving to be about 4 mm. long and quite firmly imbedded in the true skin. I make this note of the case because, so far as I know, it is unique.

Instructor in Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine.

ORIGINAL LECTURES.

SOME PHASES OF RHEUMATISM.

A Clinical Lecture delivered at the Philadelphia Hospital.

BY J. H. MUSSER, M.D.,
ATTENDING PHYSICIAN.

[Reported by W. BLAIR STEWART, M.D.]

GENTLEMEN: I show you this morning a series of cases presenting common points of interest in connection with affections of the joints. It is fortunate that you can have an opportunity to observe the many varieties, here presented, of these most common ailments.

The young man whom you now see, twenty-one years of age, whose family history is good, but who has a personal history of venereal disease and of alcoholism, was well until one month ago. About that time he slept in a cold box-car and got his clothes wet. On the next morning he awakened with pain in one knee. The joint was swollen and he could not stand. This swelling was painful, but there was no fever, or at least there was none when he came under my observation three weeks ago. Rest, with no other treatment, except some local applications, was enforced. When admitted the outlines of the joint were entirely effaced. There was distinct effusion, the patella floated, and fluctuation was easily detected, but there was no increase of heat and no redness. We have, therefore, a simple inflammation of the knee-joint of obscure origin. The inflammation was certainly due to exposure, and not to traumatism, but whether it is rheumatic I cannot say positively. The absence of fever and of all evidence of a rheumatic diathesis, as well as the localization of the process in one joint, largely removes the suspicion of rheumatism. It is a case of mild inflammation with hydrarthrosis, due to cold, and must be distinguished from such local inflammatory processes as inflammation of the bursa of the patella, known as house-maid's knee, and from purulent synovitis.

In the former affection there is no swelling of the joint, but swelling of the bursa over the joint. The portion in front is very painful, and tender on pressure, and there are heat, swelling, and fluctuation. Injury of a severe character or long-continued bruising may be associated with the inflammation as a definite cause. On the other hand, the swelling which you see in this case is similar to the swelling and suppuration due to inflammation, save that there is more heat of the joint, while œdema of the skin is present, and possibly uniform redness of the surface. Purulent inflammation is accompanied by more grave general symptoms, fever is marked, and may be of a hectic type, and it rarely occurs without suppuration in other portions of the body due to pyæmia or septicæmia.

SYPHILITIC RHEUMATISM.

This patient presents a different history; the symptoms of which he complains are not confined to one joint, but many joints and other structures are involved. There is a different antecedent history attending the development of these phenomena. It is true that the boy has been subject to rheumatism from childhood, and that his

habits of life and occupation were such as to predispose to attacks of ordinary rheumatism, but we learn further that he has had gonorrhœa six times, and once a suppurating bubo. In October, 1889, he had a chancre, and, subsequently, sore-throat. The latter is the only evidence of secondary manifestations of syphilis which we can discover, and as he states that he has been subject to sore-throat since childhood, it may have been only an expression of the ordinary rheumatic diathesis.

Nearly three months ago the patient was suddenly seized with pain in the right side of his chest. This was followed in a few days by pain in one leg. The pain in the leg was very severe at night, and was soon followed by pain in the other leg, in the breast-bone and in the shoulder-joint, and was accompanied by severe frontal headache. On admission, the pain in the head was so excessive that he was unable to sleep, and tossed the entire night, fretting and crying out in agony.

On examination we find that there is, as you see, very marked tenderness along the sternum; there is also some swelling and tenderness at the junction of the second rib and costal cartilage on the right side. There is some tenderness along the tibia, but no swelling or nodes on the long bones or the clavicles. I find no changes in the shoulder-joints, although they have been painful since the onset of the disease. When I tap the frontal bone there is marked tenderness. The pains in these localities, as I said, are worse at night. They are not lancinating or much increased by movement, but are grinding, boring pains. The general symptoms that accompany the pains are not marked. There is no fever and no disturbance of the gastro-intestinal tract. There is, however, a change in the lymphatic system to which it is important to call attention, namely, enlargement of the supra-trochlear and post-cervical glands. You will observe, therefore, that we have in this case three marked factors, which must be considered in determining the cause of the arthritic and osteal changes. There is undoubtedly a marked rheumatic diathesis present in the individual. On examination of the heart I find, however, no evidence that the rheumatic storm ever included the endocardium in its vortex. The absence of the anæmia that attends, or that rapidly ensues in cases of true rheumatism, and the persistence of the inflammatory process in the joints which were first affected, lead one to exclude the non-infective forms of rheumatism. When I say non-infective, however, I must speak cautiously, for investigations, not only of bacteriologists, but also of clinicians, seem to show the infectious origin of all cases of rheumatism. The foregoing considerations, with the positive involvement of the periosteum and the occurrence of the pain at night, characteristic of another form of infection, lead one to exclude at once simple rheumatism. The influence of the repeated attacks of gonorrhœa need not be considered, for the affection of the joints is unlike that of gonorrhœal rheumatism, as I will show you in another case.

We have, then, to discuss the relation of this man's illness to the manifest syphilitic infection. That syphilis is the cause of this illness can scarcely be gainsaid, when we call to mind, first, the character of the pains and their location; second, the fact that they are increased at night; third, their association with periosteal inflammation; and, finally, the association with them of enlargement of the lymphatic glands, which indicates an infection of the system. These symptoms tally well with our knowledge of the course and phenomena of syphititic rheumatism. I have been able to apply the therapeutic test since the patient entered the ward, and he has been very much relieved by the use of the remedy which always promptly relieves this affection; I mean the iodide of potassium. The drug has been administered freely during the last forty-eight hours, and his head-pain has improved very much, while the joint and periosteal pain is also much lessened.

GONORRHŒAL RHEUMATISM.

The next patient, thirty-two years of age, is a man who at one time, as you can readily see, was of good physique, but who is now considerably emaciated and strikingly anæmic. He was admitted into the hospital on June 27th, presenting a good family history and a record of good health until two and a half years before admission. In 1884 he had gonorrhœa, and in the fall of that year had, for the first time, a slight attack of rheumatism. In 1888 he had a second attack of gonorrhœa, and in 1889 his rheumatism began. At this time he had inflammation in the right hip and knee, and the latter joint was swollen. He was then in the Pennsylvania Hospital for six weeks, and was discharged apparently cured. He soon had a recurrence, however, of the joint trouble, the right knee usually being the seat of the most severe pain and of marked swelling. The occurrence of these attacks of rheumatism prior to admission lead us to inquire more closely, before making a physical examination, into the previous history of the patient, with the view particularly to determine whether he was subject to any ailments in childhood or later life which are manifestations of the rheumatic diathesis. I find an entire absence of indications of this diathesis both in the history and in the lesions now present which mark the remains of previous rheumatic attacks. He has never been subject to sore-throat or to quinsy; he never has had erythemas, or chorea, and he had no joint-symptoms whatever in early life. There are no rheumatic nodules, nor is there any cardiac lesion. Observe, therefore, that the present rheumatic symptoms developed after the occurrence of a specific infection in a man who had never had any form of rheumatism and who was reaching the time of life when inflammatory rheumatism is not likely to develop.

On examination there are some features of the joint-inflammation worthy of study. The inflammation has been almost entirely limited to the right knee, the second phalangeal joint of the forefinger of the right hand, the right shoulder and the right hip. There is very severe pain on moving the shoulder-joint, but I find no evidence of inflammatory change. The hip-joint is also painful on movement, and there is marked tenderness on pressure. The knee and phalangeal joint we can study more closely. The whole of the knee-joint is swollen, slight fluctuation can be readily detected, and the patella floats. On pressure, there is found a point of pain. The joint is quite stiff and the tissues around are pale and, though not œdematous, seem markedly infiltrated. This infiltration of the tissues about the joint is especially distinct at the phalangeal articulation; here, too, there is swelling, stiffness, and

pain on movement, but more strikingly thickening and infiltration of the tissues. There seems to be slight fluctuation. This joint has been the seat of persistent pain, and, indeed, has from the onset been the one particularly affected. The knee has at no time been free from pain as other joints became involved. This fact, with the local changes about the joint and the general symptoms, are, to me, sufficiently marked factors to confirm my belief that the rheumatism is of the infective form, and secondary to gonorrhœa. Observe the record of temperature, which has been carefully taken: the first week after admission there was no marked intermittency, but the temperature remained high—102° to 103°—until rest, diet, warmth and attention to the secretions caused the perturbed system to become quiet. When all complications outside of the rheumatic manifestations were removed, the temperature became regularly intermittent. A morning rise and an evening fall has continued, the intermitting character being persistent, although there has been a gradual decline both in morning and evening temperature, so that now the latter does not rise higher than 100°. This character of temperature is usually seen in gonorrhœal rheumatism. In addition, a manifestation or rather an accompaniment of gonorrhœa and gonorrhœal rheumatism is present to corroborate our opinion. The patient now has a mild ophthalmia, and has had severe attacks of conjunctivitis, undoubtedly of gonorrhœal origin.

SUB-ACUTE INFLAMMATORY RHEUMATISM.

In the same ward with these cases there is another patient with somewhat similar symptoms. His antecedent history is not less striking, but the present phenomena, while showing similarity in that the joints are involved in the disease, differ in many important particulars. The patient is a man twenty-one years of age, of good habits and without a history of venereal disease. He has never followed an occupation which is alleged to predispose to rheumatism. His previous medical history is of special interest. Ten years ago he had an attack of rheumatism in which all the joints were affected and which lasted seven and a half months. Two years afterward—in 1882—he had a second attack, a third in 1884, a fourth in 1885, and a fifth in 1886 in which the legs were affected. Last year he had a sixth attack, which lasted ten weeks, while this year he has had two attacks, the last of which began two months ago. After the third attack the bones of the ankles and toes became slightly ankylosed and their ends enlarged. The striking features of the present attack are fever of a mild type, not rising higher than 101°, and acid sweats. These sweats persist at present, breaking out profusely three or four times daily, but increased action of the skin may be noted at any time if the bedclothes are removed. His underclothing is always slightly damp, and the peculiar exhalations are readily detected. The urine is scanty, very acid, of high specific gravity, high-colored and loaded with urates and uric acid. The joints affected since he has been under observation have varied; at first the ankle-joints were involved, then one elbow, then the knees, and finally other joints. During the two months that he has been under observation all the joints have been once or twice the seat of pain, with swelling, and some heat, but no fluctuation. As you see him now, the pain is most marked in the hips.

On physical examination of the heart, I find a slight thrill and a murmurish sound which appears to indicate an old obstructive lesion at the mitral orifice. You can readily see, and the blood-count shows, that the anæmia which attends repeated or prolonged attacks of rheumatism has taken place. The pallor of the face and mucous membranes, as well as of the fingers, is marked. The blood shows a reduction of the red cells of about 1,000,000—to 3,000,000, per cm.—and a diminution of hæmoglobin of 45 per cent.

It is not difficult to recognize in this case all the manifestations of rheumatism of a subacute type.

I do not know of any group of cases that more forcibly illustrates the importance of getting definite and accurate information regarding the previous history and pathological antecedents of the patient. On the whole, as a class, if looked at superficially, the symptoms in these cases were much alike, and the true recognition of the exact nature of the illness was made possible only by the knowledge of the previous history, as well as the evolution of the present disorder. Exposure, gonorrhœal infection, syphilitic infection, and the rheumatic diathesis antedated each ailment respectively, and indicated not only for diagnostic but for therapeutic purposes the nature of the affection in each individual.

As intimated previously, the knowledge thus acquired is absolutely essential for the proper management of a case. The special cause of the disturbance indicates the means for its relief. Rest and cold or sedative applications were sufficient for the case of hydrarthrosis. A blister might possibly have hastened absorption, while, later, stimulating applications will be of service. Except attention to the functions of the various organs, no internal medication was necessary. So, too, the indication for the treatment of the case of syphilitic rheumatism was clear, and since the patient has been subjected to specific treatment he has improved rapidly. Twenty grains of the iodide of potassium were administered three times daily. Minute doses of the bichloride of mercury will be added later. Not so easy, however, is the treatment of the case of gonorrhœal rheumatism. Such cases are most obstinate. Their long continuance is probably due to persistent infection; it is therefore necessary first to use local means of treatment that diminish urethral discharge and allay urethral inflammation. For this purpose, antiseptic drugs must be employed both internally and locally. We have in one drug, fortunately, a remedy which seems to meet many indications—that is, salol. It is a good drug for rheumatism. It renders the urine alkaline and prevents it from becoming ammoniacal, and at the same time because it is excreted in the form of carbolic acid almost continuously disinfects the urinary passages beyond the urethra. Theoretically, therefore, it would be of the utmost service in all cases of gonorrhœal rheumatism. In addition, local antiseptic means should be used, and if there are urethritis or inflammatory patches, applications should be made directly to them. To detail these methods would go beyond the bounds of this lecture; it is sufficient to refer to them. The other internal remedies advocated for this form of rheumatism are not satisfactory. It is thought that the iodide of potassium is the most potent of all, and no doubt cases have rapidly improved under its administration. It was used in this case

without brilliant results. Often we must take into consideration, just as it was necessary in this case, the general condition of the patient, and base our therapeutic means largely upon indications derived from this state. The nutrition of the patient, the presence or absence of anæmia, and the state of the digestive apparatus all must be inquired into, and each furnishes an indication for treatment. Notably in this form of rheumatism it should be remembered that the patient must be nourished to the highest possible point. You readily see the flabbiness of the tissues, while the reduction of weight and the marked anæmia show that nutrition has been lowered. And I may tell you that no relief of symptoms was secured, not even any diminution in temperature or modification in the type (pyæmic), was observed until the diet of the patient was entirely changed and the most concentrated and nutritious food administered. The diet *par excellence* for these cases is, of course, a milk diet; but when the digestion is good albuminoids of all forms may be used, and hence not only milk but eggs, properly prepared meats, game, oysters, and fish are to be used, and such green or succulent vegetables as are easy of digestion. I fancy that in most of these cases the exclusion of the carbohydrates is important. Starches and sugars in any form, therefore, are not admissible. Since the diet of this man was increased and its character changed, he has gained weight and strength. His rheumatism has markedly improved and the fever has gradually fallen to the norm.

The treatment of the fourth case requires considerable judgment. Of course due attention in these cases also must be paid to the diet, and food somewhat similar to that previously indicated must be used. The peripheral circulation is somewhat at fault, as shown by the cold and bluish extremities, and massage can be employed over the structures that are not the seat of actual inflammation. The anæmic appearance of the patient indicates the use of iron, and there are many therapeutists who would advocate its employment. I am guided very largely by the condition of the urine as to the class of drugs selected, independently of the state of the blood. It seems to me a safe rule that as long as the urine is persistently acid and high colored and of high specific gravity, containing urates and uric acid in excess, it is absolutely necessary to use alkaline medication in some form, or the empiric medication by which we have been able of late years to control the rheumatic process. Hence, alkalies, salicylic acid or its compounds, or the oil of gaultheria, may be employed. I would prefer to use 10 grains of salicylate of sodium every two hours in mint-water with a small amount of whiskey, and persist in the use of the drug until its physiological effects were produced, or relief from the symptoms occurred. I very frequently add to each dose of the salicylate of sodium 5 grains of the bicarbonate of potassium. If the salicylates are not used, and they are often unsuitable because of the condition of the stomach, simple alkalies are indicated. The use of the bicarbonate of potassium, the ordinary neutral mixture, or the iodide of potassium, is of service. These drugs should be given in such doses as would produce within forty-eight hours an alkalinity of the urine. There is no reason why, with the specifics or with the alkalies, some tonic remedies cannot be employed, such as iron, quinine, or strychnine, alone or combined.

This patient improved somewhat with the administration of salicylate of sodium, but on the advent of damp weather he would have a recurrence of pain. The physiological effect of the salicylate did not persist as it should, and it was thought advisable to use the drug in large doses during a short period of time, alternating with the alkalies. The method employed is about as follows: 15 grains of the salicylate of sodium are given every two hours for eighteen hours; the succeeding day it is replaced by large doses of neutral mixture (½ ounce), and is returned to on the third day for another eighteen hours, smaller doses being given. The method thus used in this case has been most satisfactory, and the patient is much more comfortable, although the case is, from its type, subacute and protracted, and the fact that the patient has had so many previous attacks renders it most difficult to cure the disease.

As soon as the urine becomes persistently alkaline, the remedies indicated can be withdrawn and iron substituted for them. With the iron a laxative alkaline-water may be freely used.

We must recognize the influence of diet. I am confident that a well-regulated, properly chosen diet is essential to procure permanent relief. It should be used for a long time after convalescence, and be one that excludes starches and sugars, and admits of fats in moderation.

HYPERTROPHY OF THE PHARYNGEAL TONSIL.

A Clinical Lecture
delivered at the Rush Medical College,
October 30, 1890.

BY E FLETCHER INGALS, A.M., M.D.,
PROFESSOR OF LARYNGOLOGY IN THE RUSH MEDICAL COLLEGE, AND OF DISEASES OF THE THROAT AND CHEST IN THE WOMAN'S MEDICAL COLLEGE OF CHICAGO, ETC.

Synonymes: Hypertrophy of Luschka's tonsil, adenoid growths in the vault of the pharynx.

This affection consists of an abnormal enlargement of the glandular tissue normally found in the vault of the pharynx. It is characterized by obstruction to nasal respiration, alterations in the voice, and in many cases partial deafness, with catarrhal symptoms and more or less deterioration of the general health.

It is most frequently observed in damp climates and in young children, but it is sometimes met with in young adults.

Anatomical and pathological characteristics.—The changes in the glandular tissue closely resemble those which are frequently seen in the faucial tonsil. The structure is of a grayish or pinkish hue, though sometimes of a bright-red color. The surface is never granular, but often has a lobulated appearance. Enlarged bloodvessels are not present upon the surface, as in many other abnormal growths. The growth may be either soft and friable or exceedingly firm; it consists of lymphoid tissue and an overgrowth of connective tissue similar to that found in hypertrophy of the faucial tonsil. The effect upon the general health depends upon the size and shape of the growth, and the amount of obstruction to respiration.

Etiology.—Heredity undoubtedly bears some part in the etiology of this affection, yet the disease has been understood for so short a time that it is impossible to determine whether the parents of most patients have suffered from a similar complaint. Frequently, how-

ever, several children in the same family will be found so affected. It appears to be due in the majority of cases to the same causes as enlargement of the faucial tonsils. The exanthematous diseases and diphtheria occupy a prominent place in its etiology. Frequent colds, and the strumous and rheumatic diatheses, may also be reckoned among the causes. McDonald[1] attributes the majority of cases to obstruction of the nasal passages and consequent rarefaction of the air in the naso-pharynx during inspiration. This, however, would seem to be opposed by the fact that nearly all cases of cleft palate are also affected by this disease. It certainly does not correspond with my own observation, although it is true that in a considerable number of cases anterior nasal stenosis does exist.

Symptomatology.—There is usually a history of mouth-breathing, with all its attendant symptoms, extending over several months or even years, during which time the parents have been continually disturbed at night by the loud snoring and irregular and noisy breathing of the patient. The child is usually restless and often wakes from troubled dreams during the early part of the night, but toward morning sinks into a heavy sleep from which it awakens with headache or a feeling of malaise that does not wear off for several hours. Nasal or post-nasal catarrh and partial deafness are not infrequently present, and it is common to find that these diseases have come on after diphtheria or one of the exanthematous diseases which has caused hypertrophy of the gland. The defective hearing appears to result from obstruction of the Eustachian tube, and in some cases gradual extension of the inflammation to the middle ear. The deafness is sometimes outgrown as the glands atrophy during advancing life, and it may often be cured by removal of the abnormal tissue, but if allowed to persist for a long time is likely to become permanent. The voice is thick and indistinct in proportion to the interference with nasal resonance, and it becomes impossible for the patient to pronounce the letters *m* or *n*, so that *b* is used instead of *m*, and *d* instead of *n*. In such cases the voice sounds as though the patient had a cold in the head. Shortness of breath upon exertion is often noticed, and in children who are trained to keep the mouth closed, catching or sighing respiration at intervals in order to compensate for the constant deficiency of air is frequently observed. A barking, reflex cough is sometimes present. Frequently a peculiarly disagreeable nasal secretion becomes a fixed condition, and it is often necessary for these patients to clear out the naso-pharynx by the act of hawking. Occasionally, though not in the majority of cases, a rhinorrhœa is present. The nostrils and anterior nasal cavities are found abnormally small in some cases, and in the majority the faucial tonsils are also enlarged. The uvula, pillars of the fauces, and edge of the palate are generally slightly congested, and frothy or muco-purulent secretions are found upon the pharyngeal walls, dropping from the naso-pharynx. In many cases the pharynx is relaxed and the follicles swollen, as in advanced cases of follicular pharyngitis. The follicles, which are usually paler than the surrounding mucous membrane, generally increase in size toward the upper part of the pharynx until just above the edge of the palate they become continuous with the glandular enlargement. With the rhinoscope we should especially examine the posterior pharyngeal wall, the vault of the pharynx, and the choanæ, irregularity of the upper outlines of which is among the most easily recognized signs of the disease. Upon the pharynx the growth has a clearly-defined cushion-like appearance, and is more or less nodular, but in rare instances it hangs from the vault of the pharynx in soft pendulous masses resembling condylomatous warts. In color it is usually pale pink or grayish, but it may have any shade from gray to a deep red. Its surface is never traversed by bloodvessels. In adults in whom atrophy has taken place the remains of the gland may sometimes be seen as small excrescences.

Palpation is often desirable in adults to determine the consistence of the growth, and it is nearly always essential in children, because of the difficulty of rhinoscopic examination. In performing it a gag should be placed between the teeth, and the forefinger of the right hand carried back to the pharyngeal wall and then turned upward behind the palate, where it will at once detect the abnormal growth. Those unfamiliar with the normal feeling of the part should at first search for the septum and move the tip of the finger backward and upward from both sides. Slight bleeding usually follows, though the examination is not especially painful to the patient.

Chronic pharyngitis, rhinitis, or laryngitis will be found in some cases, and occasionally deformity of the thorax will have resulted in the pyriform chest or pigeon-breast.

Diagnosis.—The affection is to be distinguished from nasal mucous polypi, and from fibroid tumors. Mucous polypi seldom occur at so early an age as does hypertrophy of the pharyngeal tonsil, are of a lighter color, semi-translucent, and usually have bloodvessels coursing across their surface. They almost universally grow from the nasal cavities instead of the naso-pharynx, and may be readily detected by anterior rhinoscopy.

Fibroid tumors are much harder than the hypertrophied glandular tissue we are now considering, are frequently attended by severe epistaxis, and upon being touched bleed easily and profusely. They are usually of a bright-red color, and bloodvessels may be seen upon their surface; when large the neighboring parts are distorted—none of these signs being observed in hypertrophy of the pharyngeal tonsil.

Prognosis.—If left to themselves it is probable that in seventy-five per cent. of the cases the gland would atrophy at about the twelfth or fourteenth year of the patient's age, but in the meantime irreparable mischief to the ear, the voice, or the general health may result. In nearly all of the remaining cases the gland would gradually diminish in size and finally disappear before middle life. When the affection has existed for a long time the hearing may be permanently impaired, but, usually, removal of the gland greatly benefits the patients. The natural voice is not always immediately restored, because a person having learned to talk with an obstruction in the naso-pharynx may require a considerable time to overcome the muscular habit, and in adults it may never be entirely remedied. The results of operative procedure, if not too long delayed, are most satisfactory.

Treatment.—Of internal remedies I have occasionally

[1] Diseases of the Nose, 1890, p. 235.

found the syrup of the iodide of iron of value, particularly in anæmic children. Other preparations of the iodides will doubtless prove beneficial in a few cases, and the chloride of calcium might cause some reduction of the gland in other instances; but, as a rule, medicinal treatment is of no value. Locally, astringents have been recommended, and seem to be useful in a few cases.

The most satisfactory results follow the removal of the gland by surgical measures. In a few cases in which the friends have objected to an operation, I have employed chromic acid successfully. In using this caustic I fuse a few crystals on the end of a flat aluminum probe, and pass this through the nostril to the enlarged pharyngeal tonsil, where it is held for two or three seconds. The nares must be previously oiled to prevent the contact of any of the acid with the mucous membrane, and a small amount of cocaine may be applied to the nares and naso-pharynx in the form of either powder or spray. Applied in this way the acid usually causes a moderate amount of pain at the time and some soreness for several hours afterward, but the pain is not severe. The applications may be repeated at intervals of from three to five days, being made alternately through the opposite nostrils. The galvano-cautery may be used by means of a bent electrode passed up behind the alate, or a straight one through the naris, but the method is painful, tedious, and not very satisfactory. Scraping off the gland by means of a long finger-nail, or by various forms of curettes (Fig. 1) is in favor with some operators, and may in certain cases serve an excellent purpose; but usually the operation is less complete than when performed by Loewenberg's forceps, and, therefore, recurrence is more likely to take place. Écrasement by means of a bent snare has been practised satisfactorily in some cases in which the growth was very soft. Some operators prefer scissor- or punch-like forceps, but both are open to objections and do not seem to me to compare with the Loewenberg forceps (Fig. 2). The scissor-like instruments which I have seen may be satisfactory for cutting out a soft portion of the mass, but they are not well adapted to a complete extirpation of the growth, and other instruments will generally have to be used if the diseased mass is completely removed. The punch-like forceps are not open to this objection, but it is claimed that much more bleeding results from their use than from the instrument about to be described. By far the most satisfactory inst rument for the operation is Loewenberg's forceps, or some of its modifications. The modification of this instrument, suggested by John N. Mackenzie, of Baltimore, has proved most satisfactory to me, though I have had made a similar instrument with shorter blades for operating upon young children; these two answer the purpose perfectly.

In performing this operation upon adults it is often sufficient to anæsthetize the parts by cocaine, which may be applied by an atomizer, syringe, or swab, or by means of a hypodermic syringe with a bent needle, by which it may be injected directly into the gland. My own custom has been to apply a ten-per-cent. solution as a spray behind the palate, and a similar solution by means of a syringe with a long nozzle to the upper part of the gland through the nares.

The application should be repeated about once a minute until the part is anæsthetized, or in about ten minutes. A self-retaining palate retractor should then be inserted, and the patient may depress his tongue with a depressor. The forceps are then inserted with the aid of a rhinoscopic mirror, and thus one or two bites may be made accurately, but subsequently the blood obstructs the view and the remainder of the operation may be postponed to another sitting, or completed by the sense of touch if the patient will permit. Usually, even with cocaine, after two or three bites have been made, patients prefer to postpone the remainder of the operation. Two or three sittings, however, will be sufficient in the majority of cases. When an anæsthetic is

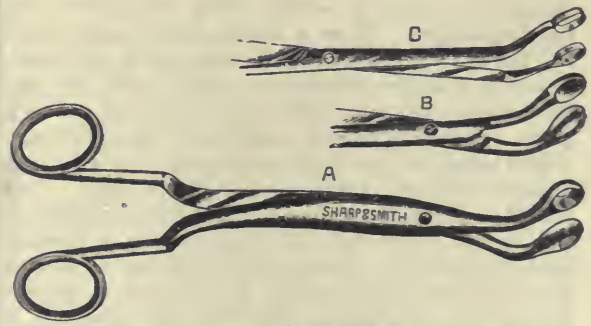
Naso-pharyngeal curettes.

FIG. 2.



Naso-pharyngeal forceps. *A*. John N. Mackenzie's modification of Loewenberg's forceps; *B*. Loewenberg's forceps; *C*. Cutting forceps.

objected to, either in adults or children, if the gland is soft, and if for any reason a perfect operation will not be permitted, a single large bite should be made, as it will give very great relief. In children chloroform or ether should be administered, chloroform being preferable. When anæsthesia is complete the child should be turned upon its abdomen and face, with its mouth over the side of the table, and a gag should be inserted to hold the teeth apart. Henrotin's gag is the simplest one for this purpose which I have seen, but sometimes Goodwille's will be found preferable, especially in large children. The surgeon, standing at the right side of the table and facing the patient's head, passes the index finger of his left hand behind the palate into the naso-

pharynx, where it is retained as a guide to the forceps. The forceps are then passed along the dorsal aspect of the finger and accurately applied to the growth. Thus the gland is removed piece by piece, the forceps being guided each time by the finger until every part has been extirpated. Care should be taken to avoid seizing the posterior edge of the vomer or the ends of the Eustachian tubes. The latter often seem to the uneducated finger like abnormal growths. If care is taken not to turn the forceps sideways there is no danger of doing damage, providing the operator is familiar with the normal condition of the parts. Sometimes masses are situated just back of the Eustachian orifices and are liable to be overlooked, but the most common difficulty arises from small pendant masses which hang just back of the choanæ and are liable to be crowded forward into the posterior nares. It is sometimes quite difficult to get the finger in front of these in order to push them back where they may be caught with the forceps. Some operators attempt to scrape them away with the finger-nail, but the effort can be only partly successful. When I find difficulty in removing this part with the post-nasal forceps, I employ a straight nasal forceps with cutting edges, which I pass through the nostril and guide to the proper point in the vault of the pharynx with my finger, which is still retained behind the palate. In this manner a piece which might otherwise be difficult to catch is very readily removed.

With the patient in the position that I have recommended there is no necessity for care in swabbing out the throat, as the blood cannot run *up* the trachea. With the patient on his back and the head thrown far backward, as recommended by some English surgeons, it is necessary to swab out the throat and naso-pharynx frequently in order to prevent blood from getting into the air-passages. There is usually considerable bleeding, but this stops as soon as the operation is completed. However, if undue hæmorrhage should occur, the posterior nares may be packed in the usual way, or, as I prefer, with a long strip of gauze which is saturated with a thick solution of tannic and gallic acids, such as I have recommended for checking nasal hæmorrhage. This should be pushed back through the naris and packed up behind the palate with the finger, which is inserted through the mouth. The nares should also be packed and the gauze brought forward to the nostril, to prevent the packing from falling down into the throat. If it should become necessary to plug the naso-pharynx, the packing should be removed from within twelve to twenty-four hours.

When the operation is completed the mouth should be wiped out and the nostril squeezed to press out as much blood as possible, but it is neither necessary nor desirable to wash out the parts. The patient should then be placed in bed and the friends directed to keep him as much as possible upon the face till he has thoroughly recovered from the chloroform. He should be kept in bed for a few hours, and in the house for from two days to a week, according to the weather. During this time I usually direct that insufflations be made, two or three times during the day, of a powder composed of 2 per cent. of cocaine, 50 per cent. of iodol, and 48 per cent. of sugar of milk. A simple detergent alkaline spray is not objectionable, but washes should be avoided for fear of injuring the middle ear; even sprays will sometimes find their way up the Eustachian tubes, and, therefore, unless, judging from the odor, there seems to be a special indication for them, I prefer to use simply the powder.

As the result of the operation there is usually a little soreness of the parts for a day or two, but not sufficient to interfere much with swallowing. There is sometimes a slight elevation of temperature. The improvement in breathing is marked and immediate in many cases; very often the friends become alarmed during the first night, because the child breathes so quietly. In cases with deafness, considerable improvement or a cure of this symptom may be expected within a few days or weeks, but alterations of the voice are less rapidly recovered from. Some danger of otitis media exists from the liability of blood or other fluids to pass into the Eustachian tube, but thus far no permanent bad results have come from it in my experience. If the accident occurs, continuous use of hot water in the ear, or hot water with glycerin and opium, and dry heat externally, are the best remedies that can be employed. In some cases nasal obstruction will be found to persist, and it must subsequently receive appropriate treatment.

The results of this operation are the most satisfactory of any that I have seen in the domain of special surgery. In cases in which the operation is needed—and in no others should it be recommended—the patient's general condition undergoes a revolution for the better which often astonishes even the physician, and gives the friends most unbounded satisfaction. It is not unusual for a child of from three to six years of age to gain from twenty per cent. to twenty-five per cent. in weight within five or six months after the removal of the gland. I have never seen ill results follow the operation, and think it safe to tell the friends that when properly done it is no more dangerous than is the removal of a finger.

MEDICAL PROGRESS.

New Method of Dressing the Chest in Pneumonia and Pleurisy.—DR. WILLIAM HUNT (*Annals of Gynæcology and Pædiatry*, February, 1891) gives the following directions for treating the chest-walls in pneumonia and pleurisy:

If there is to be any cupping or other preliminary operation, have that attended to; then all the ingredients wanted are pure collodion and absorbent cotton in smooth layers, and a good broad brush like a mucilage brush.

Apply a very thin layer of cotton over the affected side, from spinal column to sternum, and secure it with collodion smeared thoroughly over it. Then go on with thicker layers, securing them with collodion until a good padding is obtained, paying particular attention to the edges. In double cases the dressing may encircle the chest. The advantages are:

1. The one dressing, if well applied, will last throughout the case, and hence,

2. The fatigue and discomfort of frequent poulticing are avoided.

3. The side, in unilateral cases, is held as in a splint,

while the free side does the breathing. A first-class non-conductor is covering the chest. The contracting collodion may have some influence in controlling the blood-supply.

4. There is no particular interference with physical examination, to one who has a good ear. May be it would be a good thing if there was; for, having once made the diagnosis, what is the use of exhausting the patient every day by trying to find out whether one-eighth of an inch, more or less, is involved? The general symptoms will tell that.

Prescriptions for Constipation of Pregnancy.—The following prescriptions are given by the *Revue Général de Clinique et de Therapeutique* for this condition:

℞.—Rhubarb . . . . 2½ drachms.
Boiling water . . . 4 ounces.

Make into an infusion and add carbonate of magnesium 2½ drachms, and manna 1 drachm. Order a tablespoonful of this every hour.

℞.—Phosphate of sodium . . 6 drachms.
Distilled water . . . 4 ounces.
Syrup of raspberry . . 6 drachms.

A dessertspoonful of this may be given every half hour or hour.

Finally, if acidity of the stomach exists, the following may be given:

℞.—Calcined magnesium . 2½ drachms.
Manna . . . . 1 drachm.
Distilled water . . . 8 ounces.

A tablespoonful every hour until a purgative effect is produced.

Cantharidal Collodion.—The following method of preparing cantharidal collodion is noted by the *Revue General de Clinique et de Therapeutique:*

℞.—Cantharidin . . . 15 grains.
Castor oil . . . . 1½ ounces.
Acetone . . . . 1½ "
Tincture of cannabis indica 2½ drachms.
Collodion . . . . 1½ pints.

The cantharidin is to be powdered and dissolved in the castor oil with the aid of heat. After it is cooled the acetone and the collodion, and finally the tincture of cannabis indica, are to be added.

Anæsthetic Mixtures.—The following formulæ for the preparation of the anæsthetic mixtures, are given in the *Medicinische-chirurgische Rundschau.* The A. C. E. mixture, according to this journal, is made by taking:

℞.—Alcohol . . . . . 1 part.
Chloroform . . . . . 2 parts.
Ether . . . . . 3 "

Another method of making it is to use:

℞.—Alcohol and ether . . . 1 part.
Chloroform . . . . . 3 parts.

With some the anæsthetic mixture is made by adding 4 parts of chloroform to 1 part of alcohol.

Powder for Acute Eczema.—*La Semaine Médical* gives the following prescription of Alexinski for this condition:

℞.—Oxide of zinc . . . 15 grains.
Subnitrate of bismuth . 30 "
Powdered starch . . . 1½ drachms.
Powdered lycopodium . 1½ "

This powder is to be dusted over the parts which are affected, night and morning.

Aristol for Fissured Nipples.—Vinay, in *Lyon Médical,* has recommended the employment of aristol in the treatment of fissured nipples occurring during lactation. He uses it in cases in which there is much ulceration and pain. The mixture is as follows:

℞.—Aristol . . . . . 1 drachm.
Liquid vaseline . . . . 5 drachms.

This is to be applied to the breast and carefully wiped off before the child nurses. After its employment the pain diminishes and cicatrization goes on rapidly. In cases in which the glands become much involved this preparation of aristol may be rubbed into the enlargements with advantage.

Cystitis in Women.—The *Journal de Médecine de Paris* gives the following prescription for cystitis in women:

℞.—Citrate of potassium . . . . ½ ounce.
Fluid extract of triticum repens } of each 1 "
Tincture of belladonna }
Fluid extract of buchu . . . ½ "
Water, a sufficient quantity to make 4 ounces.

A teaspoonful in a wineglassful of water three times a day.

Treatment of Diphtheria by Mercurial Inunctions.—In *La Semaine Médical* Smakovski states that he has employed frictions of mercurial ointment in a number of cases of diphtheria with great success. The inunctions are continued until marked evidences of mercurialism are present, and it may even be necessary to use a mouth-wash of chlorate of potassium in order to prevent salivation. This treatment, of course, is identical in its effects with the exceedingly common method of using calomel or bichloride of mercury in this disease for the purpose of decreasing the quantity of the plastic exudate.

The Treatment of Metrorrhagia in Childbed.—Braun states that in cases of metrorrhagia occurring within sixty hours of parturition it is necessary that we should determine the condition of the uterus. If it is not firmly contracted energetic pressure should be made at once upon the fundus, and all clots removed from the vagina by the finger. If the hæmorrhage persists and continues after pressure upon the uterus, it is well to introduce a piece of ice into the vagina. If grave symptoms arise from the hæmorrhage, 1 or 2 drachms of fluid extract of ergot with 20 drops of the tincture of nux vomica may be given, and repeated in half an hour if the uterus has not contracted. Cold should be applied to the belly and used by vaginal injections. Internally it may be well to administer rum or strong wines. — *L'Union Médical.*

CURRENT LITERATURE.

SATURDAY, MARCH 21, 1891.

THE SUSPENSION TREATMENT IN LOCOMOTOR ATAXIA AND OTHER NERVOUS DISEASES.

JULIUS HESS gives a very thorough review of the suspension treatment and its literature, from 1883, when it was incidentally discovered by Motschukowsky, to the present. He, himself, has employed the treatment in eighteen cases; five of these were cases of locomotor ataxia, and eight of neurasthenia, the remaining five consisting of one case each of old neuralgia, spinal muscular atrophy, gastralgia, hypochondria, and cerebral syphilis. Three hundred suspensions were given, one patient, who had locomotor ataxia, receiving as many as eighty. The duration of the suspension at first was from one-half to one minute, and later, four minutes. Some patients were suspended every day, others every other day, and still others at irregular intervals. Pretty full abstracts of his cases are given. The patients affected with locomotor ataxia were not improved, or at least only temporarily. In the majority of the cases of neurasthenia no result was obtained. The remaining patients were either only improved transiently or were made worse. Hess admits that the experience of others has, for the most part, been more favorable, and that other methods have no better effect upon progressive locomotor ataxia. The method of suspension is convenient and time-saving, and, in the hands of a physician who chooses his cases properly and has suitable apparatus, it is not dangerous.—*Berliner klinische Wochenschrift*, February 2 and 9, 1891.

TREATMENT OF PNEUMONIA WITH LARGE DOSES OF DIGITALIS.

PROFESSOR Z. PETRESCO, of Bucharest, delivered a lecture on this subject before the Section of Internal Medicine at the last International Medical Congress. He refers to his previous remarks and to the writings of a number of others on the same subject. He uses an infusion of 60 grains of digitalis leaves to six ounces of distilled water, to which about an ounce of syrup of orange-peel is added. The digitalis is allowed to steep for a half-hour. A tablespoonful of this mixture is given every half-hour. Petresco says that doses of this size are well borne, and that he has never met with a case of poisoning, his results differing in this respect from those of other physicians. He maintains that these doses are therapeutic, not toxic, and that the absence of toxic symptoms is not due to the use of an inferior digitalis leaf. Satisfactory proof of the latter statement is furnished by giving the sources of the supply and analyses showing the strength of the leaves. Digitalis leaves infused for fifteen minutes yield to the water digitonin, digitalein, and digitalin; digitoxin does not pass into this infusion. The urine of twenty-three patients was examined, both during and seven days after treatment, and only digitalein could be detected.

The best results were obtained in fibrinous or croupous pneumonia. The results in infectious pneumonia are explained principally by the hyperkinetic, antipyretic, and antiphlogistic action of digitalis; in such cases it was used together with antiseptics. Digitalis has also been very useful in pneumonias complicated with bronchitis and pleurisy, and especially in cases associated with heart disease. Petresco declares that he has observed cases of true croupous pneumonia undoubtedly aborted by digitalis used in the way he describes. In from twenty-four to forty-eight hours, the time necessary for the development of the action of digitalis, a sudden fall of temperature from 102°, 104°, or even 106°, to 98.4°, 97°, or even 95°, has been observed. This fall of temperature was accompanied by a corresponding decrease in the frequency of the pulse and respiration, and by the usual symptoms of convalescence.

No effect upon the digestive tract was observed, except the occasional production of vomiting, which occurred especially in apical pneumonias.

The greatest and most persistent changes were noticed in the pulse, which became slow, powerful, and of high tension. Irregularity or intermittency of the pulse were never observed. A number of sphygmograms are reproduced, showing the transformation of a frequent, weak, often dicrotic pulse, of large volume, into a slow, strong, small pulse, of high tension. Petresco does not regard digitalis as a diuretic, because it exerts no direct action upon the kidneys. In dropsy of cardiac origin digitalis produces an increased flow of urine by improving the general condition of the patient. Petresco has treated pneumonia according to the expectant plan, with emetics, alcohol, bromide of potassium, caffeine, strophanthus, and convallaria, and he compares the results obtained in these cases with the results obtained by the use of large doses of digitalis. His conclusion is that the latter plan possesses decided superiority. He also quotes statistics from Jaccoud showing the mortality attending the treatment of pneumonia by bloodletting, tartar emetic, and alcohol, and that attending the expectant plan of treatment. The highest mortality (34.50 per cent. in 698 cases) occurred under employment of bloodletting, and the lowest (3 per cent. in 129 cases) under the use of tonics, alcohol, etc. In contrast with these, Petresco places the mortality statistics at the *Central Militärlazareths*, in Bucharest, which are as follows: From 1883 to July 1, 1887, there were 577 cases with a mortality of 1.21 per cent.; to January 1, 1889, 816 cases, with a mortality of 2.06 per cent.; and up to the time of his report there had been 825 cases, with a mortality of 2.06 per cent.

His general conclusions are as follows:

1. Digitalis has a direct antiphlogistic action only in therapeutic doses.

2. The specific therapeutic dose is from 60 to 120 grains of the leaves, given as an infusion, within twenty-four hours.

3. This dose may be continued from two to four days according to the severity of the cases treated.

Patients have received in the course of their disease from 300 to 360 grains in four or five days, without symptoms of nausea or poisoning. The temperature fell from one to three degrees after single doses, and five or six degrees after two or three doses. The pulse fell from 40 to 60 beats after several doses. This reduction of the frequency of the pulse and of the temperature lasts ten or twelve days, and then they gradually become normal.

4. Disappearance of all local symptoms of the pneumonia is observed simultaneously with the improvement in the circulation and respiration.

5. The effectiveness of the treatment is confirmed by the statistics, the mortality being least under large doses of digitalis.

6. The applicability and harmlessness of the therapeutic dose are incontrovertibly proved by cases reported in full by Petresco's pupils—Brailov, Sacliano, Antoniu, and Constantinesco.

7. Comparative study of the various methods of treatment of pneumonia has persuaded Petresco that the expectant plan is not only irrational, but even dangerous. The supposition that pneumonia must run its course is not justified. Pneumonia may be aborted, especially if attacked at the beginning.—*Therapeutische Monatshefte*, February, 1891.

DIFFERENTIAL DIAGNOSIS BETWEEN ULCER AND CANCER OF THE STOMACH.

Kollmar says that in the great majority of cases the diagnosis between ulcer and cancer of the stomach is easily made, but that in not rare cases it may be difficult. In some cases the course of ulcer of the stomach is without striking symptoms, and the disease is perhaps first discovered at the autopsy, or makes its presence known by sudden profuse hæmatemesis or by a perforative peritonitis. Cancer of the stomach may also exceptionally exist without peculiar characteristic symptoms, the only symptoms being a steadily progressing marasmus and profound cachexia, without any other recognizable cause. Usually, however, pronounced digestive disturbances, pain in the region of the stomach, and vomiting, with or without admixture of blood, point with certainty to serious disease of the stomach; but whether it is ulcer or cancer must be determined by other considerations.

The points to be considered in the differential diagnosis of the two diseases are, the age of the patient, the character of the pain, the character of the bleeding, the degree of acidity of the gastric juice, the duration of the disease, the condition of the nutrition of the patient, and the presence or absence in the gastric region of a palpable tumor.

As regards age, gastric ulcer is most frequent between the ages of fifteen and twenty years; but it is not rare in old persons. Cancer of the stomach is most frequent between the fortieth and sixtieth years of life, eighty-two of Kollmar's one hundred and eighteen cases occurring during this period. Kollmar's statistics of one hundred and eighteen cases of cancer seen in the last twenty years at the medical clinic at Tübingen, give an average age of fifty years.

Localized pains, "wound pains," are characteristic of gastric ulcer, but they are not present in all cases, and are found in gastric cancer in the stage of ulceration. Diffuse pains, dyspeptic discomfort, and cardialgia, are common to both diseases. The pain in gastric cancer is usually less intense than that in gastric ulcer.

Hæmatemesis varies greatly in character and quantity in both, but generally profuse hæmorrhages are more frequent in ulcer.

Absence of hydrochloric acid from the gastric juice is not an absolutely certain sign of the presence of cancer. A negative reaction is obtained in some cases of amyloid degeneration of the gastric mucous membrane, in cancer of the duodenum and œsophagus, and in poisoning with acids; and the reaction is frequently negative in gastric catarrh, in atrophy of the gastric mucous membrane, and in persistent fever. A temporary absence is not rare in gastric catarrh and dilatation of the stomach. In the latter diseases the reaction may be obtained by repeatedly washing out the stomach. Kollmar reports a case of this kind. A decidedly positive reaction speaks with considerable but not absolute certainty against the diagnosis of gastric cancer; while a negative reaction, because it occurs in other diseases of the stomach, should at least not be regarded as characteristic of cancer.

The duration of the disease is of great importance in the diagnosis. Gastric ulcer runs a very chronic course, frequently lasting years; it may get well and subsequently recur. The course of gastric cancer is different, as it is very exceptional for it to last longer than two years, and usually death occurs much sooner. A preceding history of stomach trouble lasting for years, getting well for a time and then relapsing, is against the diagnosis of cancer even in old persons.

Cancer sometimes, but very rarely develops in the scar of an old ulcer. Kollmar has been able to find only fourteen cases of this kind reported in the literature upon the subject. Details of cases by Dittrich, Meyer, Lebert, Heitler, Platow, Rosenheim, and Kulcke are given. It is not reasonable, therefore, to pay too much attention to these exceptional cases in the diagnosis. Both ulcer and cancer may both be present in one patient.

An important diagnostic point is the condition of the patient's nutrition. Great and early emaciation and cachexia occur in the great majority of cases of gastric cancer, whereas in ulcer the nutrition is often relatively good. But when the ulcer has persisted a long time, and the stomach has become dilated, and frequent vomiting and hæmorrhages occur, the picture of the disease is very much like that of cancer.

A sign, surpassing all others in diagnostic importance, is a palpable tumor in the stomach region, which is almost always present in cases of cancer. It may be simulated by scar tissue about an ulcer, by a sacculated peritoneal exudate, by an hypertrophied pylorus, or by a tumor of a neighboring organ. In such cases watching for the growth of the tumor leads to a correct decision, though in some cases increasing atrophy of the abdominal

walls, by making the tumor more readily palpable, has made it appear to grow larger. Reinhard has collected sixteen cases of simple ulcer of the stomach with tumors. In six cases the tumor was caused by an hypertrophied pylorus from cicatricial stenosis; in six it was the result of adhesions between the stomach and other organs, caused by the ulcer, and in part also by encroachment of the ulcer itself upon these organs; in three cases there were foreign bodies in the ulcer; and in one case an encapsulated abscess. All the sixteen patients were of an age at which cancers are common; thirteen were women and three men. A tumor of the head of the pancreas may lead to error. In such cases as Reinhard's, the duration of the disease is a great aid in the diagnosis.

Kollmar concludes his paper by reporting three interesting cases. In the first case, a woman forty-eight years old had suffered from gastric ulcer for thirteen years. Subsequently a marked tumor and severe cachexia appeared, so that it was supposed that a cancer had developed. The autopsy revealed a gastric ulcer, but no cancer was found. The second case was that of a woman forty-six years old who had had disease of the stomach for twenty-three years. A diagnosis of gastric ulcer was made in spite of the presence of the gravest cachexia, a decided tumor, and the absence of hydrochloric acid in the gastric contents. This diagnosis was confirmed by the autopsy. In the third case, a woman fifty-three years old, with the gravest anæmia and cachexia, had had disease of the stomach for a great many years. The diagnosis was gastric ulcer without carcinoma, and was confirmed by autopsy.—*Berliner klin. Wochenschrift*, February 2 and 9, 1891.

MERCURIAL STOMATITIS.

IN writing upon the subject of mercurial stomatitis FOURNIER[1] claims that every time that mercury is administered it is at the risk of developing stomatitis. All the mercurial compounds, however, are not equally dangerous in this respect, and the mode of administration also has a bearing upon the production of stomatitis. The administration of mercury by inunctions is the mode which predisposes most markedly to this complication. If properly made—that is, not extending the application over a longer space of time than ten minutes, or using a larger amount than one drachm—inunctions are generally well borne; notwithstanding, it is necessary to watch the gums. If used in larger amounts than one drachm, even one and a half drachms *per diem*, salivation is apt to occur. This stomatitis is abrupt in appearance, and is more intense at first than that which follows the administration of the drug by the mouth. Fournier claims that the hypodermic injection of mercury, which was formerly believed to be free from the danger of producing salivation, is usually followed by disastrous effects within a few days.

There are certain conditions favoring the appearance of stomatitis during the administration of any of the preparations of mercury. Among these are *idiosyncrasy* and *a bad state of the mouth*, with a tendency to stomatitis. It is wise, therefore, to inquire into the history of the patient as to any susceptibility to mercury, and, in all cases, to make an examination of the mouth. The presence of the teeth is also a factor in the production of a stomatitis of this kind. Salivation never occurs in the newborn, nor does it occur in toothless old people. Workers in mercury mines suffer from frightful attacks of stomatitis until they lose their teeth, after which they have no further trouble. Sex, also, has a peculiar influence, women being much more susceptible than men to the effects of the drug. Denudation of the skin is a marked predisposing cause, and the dressing of vulvar mucous patches with a mercurial pomade has frequently resulted in an inflammation of the mouth. The genital surfaces are especially sensitive to the action of mercury, and a single inunction upon the scrotum may determine a stomatitis.

CANCER OF THE PANCREAS.

N. MUSMECI, in a paper entitled "A Contribution to the Pathology of Cancer of the Pancreas," says that it is often impossible to determine clearly cancerous degeneration. The rarity of this alteration in an organ the functions of which are so poorly understood, and which is in such close proximity to the stomach, the liver, the intestines, and other organs, renders a diagnosis with absolute precision most difficult. Musmeci, with great clearness, has drawn from his studies the following conclusions:

1. The diagnosis of cancer of the pancreas, in the majority of cases, is difficult; it frequently happens that the disease is confounded with neoplasms of other organs.

2. Diagnosis by exclusion is the best method in diseases of this organ in general, and in carcinoma in particular.

3. Jaundice in the beginning of the sickness, the presence of a tumor which corresponds in its location to the pancreas, the presence of fatty material in the fæces and of sugar in the urine, have a considerable supposititious force in the diagnosis of a cancerous affection.

4 The vicinity of the pancreas to the principal abdominal organs increases the liability of the transmission of the cancerous germs from one organ to another in the great majority of cases, and there is no method of ascertaining whether the alteration began in the pancreas, liver, stomach, or other abdominal viscera.—*Gazetta degli Ospitali*, Nos. 82 and 83.

NATURE, ETIOLOGY, AND TREATMENT OF SCROFULA.

SCROFULA was considered for a long time as a disease (Lugol) with a prodromal period which was designated the "scrofulous habitus." The course of the disease was divided into four periods: The first was characterized by the appearance of eczema, impetigo, nephritis, chronic coryza, otorrhœa, en-

larged tonsils, and acute suppurating adenitis. The distinguishing characteristics of the second stage were various affections of the skin and mucous membranes, followed by exuberant ulcers, and chronic suppurating cervical adenitis, leaving fistulæ and depressed cicatrices. In the third period were grouped cold abscesses, glandular enlargements, periostitis, hyperostoses, caries, necrosis, and "white swellings." The fourth period comprised diseases of the viscera, bronchial, pulmonary, and pleural tuberculosis, scrofulous lesions of the prostate, bladder, kidneys, testicles, ovaries, vertebræ, and brain, together with amyloid degenerations.

This theory has been entirely abandoned, owing to the advance in bacteriology and pathology during the past thirty years. To-day we recognize the scrofulous diathesis, a condition which predisposes to certain affections, such as the dermatoses and catarrh of different organs, which, however, are not specific, as was formerly believed. These different diseases do not at first present anything peculiar in their symptoms and development, but at length it will be noticed that their progress is not as frank as it should be, the inflamed parts become hypertrophied and tumefied, resolution not being complete. The disease has a tendency to become chronic, in which state the least cause gives rise to a subacute condition. There is thus established a predisposition which renders more easy the development of scrofulous diseases, catarrhs, inflammations of the skin and mucous membranes, which, by their repetition and chronic tendency, produce the so-called "scrofulous habitus." Associated with this diathesis there is thickening of the upper lip and alæ of the nose. There is, however, nothing specific in this condition. As to the causes of this diathesis: First, it is hereditary in the full meaning of this term—a scrofulous parent transmits the disease to his child. Second, the general condition of the parents at the time of the procreation of the child exerts an influence upon the nature of its tissues and their future nutrition. An aged, sick, or syphilitic father may engender a scrofulous child, while sickness, persistent vomiting, or hæmorrhages in the mother during gestation may have the same influence upon her offspring.

Again, the scrofulous diathesis may be acquired during the first months of a child's life, through bad hygiene or sickness. It may also be induced by an artificial or incomplete lactation, either because the nurse is too old or the milk too poor, or too rich in fats. Premature feeding of a child with coarse foods, and the gastro-intestinal diseases which result from it, with their attendant symptoms of vomiting, diarrhœa, acid fermentation, and intestinal or gastric dilatation, may also induce scrofula. An interesting fact, and one which is undeniable, is the close relation existing between joint affections and scrofula. The children of gouty and diabetic people, the most typical arthritics, are often scrofulous. These children are greatly predisposed during their first years to the same diseases as are the children of scrofulous people.

As regards treatment, it is necessary to improve the nutrition, and to favor tissue change. The hygiene of the mother should be looked after during pregnancy, a good nurse should be provided for the baby, and its feeding carefully attended to. Later, the baby's food should be selected with reference to the proportion of proteids and fats. The function of the skin may be maintained by dry frictions, salt and sulphur baths during the winter, and cold baths or douches during the summer. Sunlight, exercise in the open air, alternate sojourns upon the plains and in the mountains, avoidance of damp climates, and abstinence from alcoholic as well as stimulating drinks like coffee and tea, are essential in the treatment.

The drugs to be employed are the iodides, iodoform, arsenic, iron, and tannin, which should be used alternately.—Gendre, in *Journal des Maladies Cutanées*, December, 1890.

TREATMENT OF CYSTITIS IN WOMEN.

According to Gaubet (*Archives de Tocologie et de Gynécologie*, January, 1891), the treatment of cystitis in the woman comprises: 1. Urinary antisepsis; 2. Medical treatment; 3. Medico-surgical treatment; and lastly, true surgical procedures. An antiseptic condition of the urine is best produced by the administration of salol, which, under several experienced observers, has given excellent results. The borate of sodium, according to Terrier, has given rise to gastric troubles, while the benzoate of sodium and benzoic acid have been proven to be inefficient in producing the desired effect. Bazy having tried salol, found that the drug is very well borne, even by the most delicate and rebellious stomachs, in doses of one and a half drachms, although one-half to one drachm is generally sufficient. This occasionally, not always, causes a diminution in the pain and smarting during micturition. The elimination occurs generally on the first day, but may be delayed twenty-four hours, and it may continue during one or two days, and even more, after the stoppage of the drug. The cases in which salol acts most efficaciously are the purulent catarrhs of the bladder, and in such cases it should be given in doses of from fifteen to thirty grains. Salol does not act, however, to any appreciable degree upon suppurations of the urinary passages.

Antisepsis of the urinary passages, finally, is completed by observing perfect antiseptic measures in regard to the instruments which are used. Boiling water is generally sufficient to disinfect all metallic instruments. Should the bladder require washing out, it should be done with sterilized instruments; and the fluid used should be a solution of boric acid or of dilute silver nitrate. In patients in whom the entire organism has become infected, it is necessary to prevent the infection from becoming aggravated by suppressing the cause as far as is possible. This requires a careful investigation into the condition of the bladder, the ureters and the kidneys. Secondly, elimination of the poison by the natural emunctories should be facilitated; by the skin, through the aid of sudorifics; by the kidneys, by means of revulsives over the lumbar region and large quantities

of diluent drinks. It is also necessary to destroy the poison in the system by means of quinine, and to increase the resisting powers of the patient by the use of tonics. To repeat, antisepsis of the urinary passages comprises the administration of salol in half-drachm doses daily for two or three days before the operation, intra-vesical douches of boric-acid water (3 parts to 100), and the disinfection of the instruments employed.

The medical treatment of cystitis includes primarily injections of morphia. Barley-water, linseed tea, and other diuretics will calm the pains attendant upon micturition, by freeing the urine from its irritating properties. The mineral waters have little action in the treatment of painful cystitis. Rest is an important element in the management of these cases. Opium, chloral, bromide of potassium, and belladonna should be given for the pain, and purgatives and enemata for the relief of the constipation.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, February 2, 1891.

THE PRESIDENT, WILLIAM HUNT, M.D., IN THE CHAIR.

DR. THOMAS G. MORTON reported

THREE CASES ILLUSTRATING THE RESULT OF TREATMENT OF EQUINO-VARUS.

The speaker said that the cases illustrated those forms of equino-varus which he has designated as "complicated" and "uncomplicated" equino varus. In the complicated equino-varus the foot cannot be brought to a right-angle with the leg, because the astragalus is displaced forward and more or less rotated, and in this position forms a wedge in front of the joint and so prevents flexion of the foot; in all such cases the displaced bone must be removed. In "uncomplicated" equino-varus the tarsus is almost or quite normal, the distortion resulting from contraction of the soft parts. In these cases massage, traction, and tenotomy will overcome deformity, after which the child is able to walk with the aid of appropriate apparatus.

CASE I.—Emory W., aged four years, was brought from Bedford County, Pa., to the Orthopædic Hospital, November 11, 1890, with very marked deformity and great rigidity of both feet. General tenotomy had been performed during the patient's infancy without benefit. On examination the equino-varus was found to be of the complicated variety—displacement forward with rotation of the astragalus. There was considerable atrophy of both extremities. The astragalus of each foot was excised on November 18th. The tendo Achillis and flexor tendons of the toe were divided. No vessel required ligation. Catgut was used for drainage. Right-angled tin splints and the usual dressings were employed. Walking-shoes were applied January 13th, and on January 25th his feet were in excellent position and he walked well.

CASE II.—Harry Z., aged three years, was admitted to the Orthopædic Hospital, January 15, 1891, with marked double equino-varus. Tenotomy had been performed in infancy. Examination showed no displacement of the astragalus, the distortion being entirely due to contraction of the soft parts of the feet.

General tenotomy was performed January 22d, the anterior and posterior tibial tendons, the flexor tendons of the toes, and the tendo Achillis of each foot being cut. The feet were placed in right-angled posterior tin splints, and the dressing allowed to remain undisturbed for two weeks, when the wounds were found completely healed. The club-foot walking-shoes were applied at this time and gave satisfactory results.

CASE III.—Annie S., aged eleven years, was admitted to the Orthopædic Hospital, November 29, 1890, with talipes equino-varus of the left foot. Tenotomy had been performed in early infancy without benefit.

On examination the tarsus was found normal, the distortion being due entirely to contraction of the soft parts.

On December 4th the tendo Achillis was divided and the foot readily brought to a right-angle with the leg. The varus was then overcome, and after section of the anterior and posterior tibial tendons the foot was spread out, after which all of the flexor tendons of the toes were divided. A right-angle tin splint and the usual dressings were applied to the foot. The position of the foot was excellent. An ordinary walking-shoe was applied January 15th.

DR. J. H. PACKARD said in discussion: "I desire to mention in this connection a case of talipes under my care at the Pennsylvania hospital. The patient is a Russian Jew, about twenty-five years of age. The distortion was so great that he was compelled to walk on the back of his foot. I did the operation described by Dr. Morton, dividing subcutaneously the tendo Achillis and the tendon of the anterior and posterior tibial muscles and removing the astragalus. The plantar fascia and all the flexor tendons of the toes were also severed. The foot is now in a much better position. One point to which I would call special attention is that the foot is now set further forward on the leg than normally. Instead of the weight of the body coming on the arch, it will come on the posterior abutment of the arch. There will be no spring to the gait, and the man will walk as if he had a flat foot. I do not know whether it would have been possible to avoid this condition in the treatment. The improvement in the appearance of the foot is marked, and the gait will probably be equally improved."

DR. H. AUGUSTUS WILSON said: "I hoped to have a case here this evening which I think is a proper one for the operation advocated by Dr. Morton. There are, however, in this case unfortunately several serious complications, such as spina bifida, complete sensory paralysis of one side and partial on the other, with sloughing bursitis of both feet. It has been almost impossible to stop the suppuration in the bursæ. An incision which was made six weeks ago in the foot where the anæsthesia was most marked, as yet shows no tendency to heal. It seems probable, therefore, that any extensive operation would be followed by slow healing. The spina bifida is gradually diminishing in size, being now only half as large as it was six months ago. I hope that someone can inform me as to the possibili-

ties of an open wound in a part where there is such profound anæsthesia."

Dr. Thomas G. Morton said that "occasionally we find in adults severe and painful distortion of the foot with atrophy where the usual operative measures cannot be considered, and amputation is the only resource.

"A young woman, aged twenty-six years, with a congenital equino-varus of the right foot, was admitted to the Orthopædic Hospital last December. The limb was greatly atrophied, the circulation was very defective, and three toes had sloughed off at different times, apparently from very trivial injuries. The patient had great difficulty in walking, was very lame, and suffered much pain.

"Under the circumstances, I considered an operation to correct the deformity unjustifiable. A Teale amputation was performed, being followed by slow union of the flaps, but no suppuration."

Dr. J. H. Packard then showed specimens of

SEPARATION OF THE EPIPHYSIS OF THE FEMUR,

taken from a boy nine years of age who was brought to St. Joseph's Hospital in April, 1889, having had his leg caught in the wheel of a carriage behind which he was clinging. At first sight the appearance was that of a luxation of the knee. A closer examination, however, showed an oblique wound across the posterior part of the knee-joint, the diaphysis of the femur, stripped of its periosteum, presenting. The epiphysis was turned over on top of the diaphysis and held in that position by the heads of the tense gastrocnemius muscle. The patella was not materially displaced, being still in relation with the joint, but was tilted up by the action of the quadriceps muscle. The vessels had not been torn, but had slipped around the end of the diaphysis, the blood in the artery being coagulated, so that there was a probability of the limb becoming gangrenous. The damage to the soft parts was so extensive that an attempt to save the limb was not considered proper. Amputation was therefore performed, about an inch and a half of the shaft being removed. The boy made a perfect recovery.

There are several interesting points in connection with separations of the epiphysis of the femur. In the first place this epiphysis is unlike all the others in regard to the mechanical disadvantage at which it is placed. The speaker has collected sixty-eight cases of this injury. There is often a tearing-off of a small portion of the diaphysis. In the case just described there is an extremely small portion of the diaphysis torn from the inner side of the shaft, which does not, however, alter the character of the injury. Separation of the epiphysis is not at all analogous to fracture of the femur, although it might simulate a fracture in cases in which there is a separation of a large splinter of bone. This might resemble fracture low down in the femur. In a fracture of this kind there is crepitus. The deformity is easily reduced and does not recur, but in cases of separation of the diaphysis there is no crepitus, because there is no contact between the separated portions of bone. In almost all, even the simple cases that have required operation, or when an examination has been made shortly after the accident, the periosteum has been found stripped from the surface of the shaft. The reason for this is plain. During extreme extension the epiphysis is strongly held by the ligaments; then when separation occurs there is violent thrusting downward of the diaphysis through a sort of button-hole in the periosteum, which is thus stripped off. In one case the periosteum is said to have been torn off as high as the trochanter. A distinguished French surgeon advises in these cases that the shaft of the femur be resected to a point as high as the separation of the periosteum. If this were carried as high as the trochanter, it would of course make the limb useless. If reduction is possible, the periosteum soon becomes re-adherent, and the nutrition of the bone is not materially interfered with.

Amputation has been done in twenty-eight of the sixty-eight cases reported. In a number of cases there were other injuries causing death in a short time, and in many others the diagnosis was not satisfactorily established. The speaker thought this was the twenty-seventh instance in which the accident was produced by catching the leg in a carriage-wheel. One case was recently reported by Owings in the *New York Medical Journal* in which amputation was not required. The difficulty in reducing the epiphysis, due to the contraction of the heads of the gastrocnemius, could be relieved by dividing the heads of the muscle. Whether the case would do well with a large open wound and section of the muscle, he could not say. In this case there certainly would have been difficulty in keeping the bone in position without resection.

In discussion Dr. John H. Brinton said that he had a specimen almost identical with that shown by Dr. Packard. The accident occurred in 1881 in the practice of Dr. Davison, of Bradford County, Pa. In the paper describing the case is the following account: "The patient was a boy twelve years of age, who, while riding on the back of a rapidly-moving wagon, caught his left foot between the spokes of the wheel. The foot was then carried to the front of the hub, and the popliteal region was violently strained between the sharp edge of the hub, the axle-shoulder, and the under cross-brace of the wagon. The patient was seen a few hours after the accident. There was an oblique wound, four or five inches long, extending across the upper part of the popliteal space; the skin, superficial fascia, and muscles were severely lacerated, and there was copious hæmorrhage, supposed at the time to be venous. The wound was dressed and the parts brought together by sutures. The diagnosis was obscure; there was vague crepitus, and the accident was believed to be a fracture of the femur near and perhaps into the knee-joint. On the following day the limb was cold, and there was still no pulsation in the artery. In four days gangrene set in, and the limb was amputated three or four inches above the knee-joint. Careful dissection showed that the epiphysis had been completely torn from the diaphysis, and the popliteal artery was injured so that a probe could with difficulty be passed through. There was also a rupture in the posterior portion of the synovial membrane of the knee-joint. The patient made a good recovery."

NEWS ITEMS.

Illinois State Board of Health.—The Illinois State Board of Health has decided that hereafter it will recognize no foreign diploma that does not confer the right to practise medicine in the country in which it was granted. The holder of an Austrian, a German, Russian, or Swiss

diploma, wishing to practise in Illinois, must hereafter pass an examination before the State Board, unless he has passed the State examination of the country from which he comes. The holder of a Canadian diploma, unless a licentiate of the Colleges of Physicians and Surgeons of Ontario and Quebec, must pass an examination before the Illinois Board in order to practise in Illinois.

Hypnotism in Public Forbidden.—The first official suppression of a public hypnotic entertainment in this country occurred at Cincinnati, where the Health Commissioner, Dr. J. W. Prendergast, advised the licensing authorities of that city that hypnotic exhibitions should be forbidden. Dr. Prendergast takes the ground that the indiscriminate application of hypnotism is in a large proportion of cases injurious to the mental health of the subjects. The Common Council has interdicted these exhibitions, and adopted an ordinance making them a misdemeanor.

Congress of Hygiene and Demography.—The aim of the Congress is to awaken public interest in the progress of hygiene and demography—by the latter term being understood the study of the life conditions of communities from a statistical point of view; to afford persons interested in these subjects an opportunity of meeting one another, with the object of advancing their progress; and, by conferences and debates, to elucidate questions relating to hygiene, demography, and public health.

The Congress will be held in London, August 10 to 17, 1891.

The Governments of all countries, municipalities, county councils, and other provincial administrations, public health authorities, universities, colleges, and all societies which are occupied in the study of the sciences more or less immediately connected with hygiene, are invited to coöperate and appoint delegates to represent them at the Congress. An exhibition of articles of hygienic interest will be held in connection with the Congress. Excursions will be arranged to various places of especial interest to hygienists.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 8 TO MARCH 16, 1891.

By direction of the Acting Secretary of War, WILLIAM C. SHANNON, *Captain and Assistant Surgeon*, now on duty at Fort Apache, Arizona Territory, will repair to this city and report in person to the Adjutant-General of the Army for further orders.—Par. 3, *S. O. 55, A. G. O., Washington*, March 11, 1891.

By direction of the Acting Secretary of War, HENRY I. RAYMOND, *Captain and Assistant Surgeon*, is relieved from duty at Newport Barracks, Kentucky, and assigned to duty at Fort Thomas, Kentucky, reporting in person to the commanding officer Fort Thomas, and by letter to the commanding general Division of the Atlantic.—Par. 18, *S. O. 54, A. G. O., Washington*, March 10, 1891.

FINLEY, JAMES A., *Captain and Assistant Surgeon*, having been found, by an Army retiring board, incapacitated for active service, on account of disability which is not the result of any incident of service, is, by direction of the President, wholly retired from the service this date, under the provisions of Sections 1252 and 1275, Revised Statutes, and his name will be henceforward omitted from the Army Register.—Par. 2, *S. O. 54, A. G. O., Washington*, March 10, 1891.

By direction of the Secretary of War, a Board of Medical Officers, to consist of EDWARD P. VOLLUM, *Colonel and Chief Medical Purveyor*; DALLAS BACHE, *Lieutenant-Colonel and Surgeon*; ALFRED C. GIRARD, *Major and Surgeon*; and CHARLES M. GANDY, *Captain and Assistant Surgeon*, is constituted to meet in New York City, on March 16, 1891, or as soon thereafter as practicable, for the examination of candidates for admission into the Medical Corps of the Army, and such other business as the Surgeon-General may desire to bring before it.—Par. 18, *S. O. 52, A. G. O., Washington, D. C.*, March 7, 1891.

RETIREMENT.

FRYER, BLENCOWE E., *Lieutenant-Colonel and Assistant Medical Purveyor*, February 24, 1891.

PROMOTIONS.

GREENLEAF, CHARLES R., *Major and Surgeon*, to be Lieutenant-Colonel and Assistant Medical Purveyor, February 24, 1891.

WINNE, CHARLES K., *Captain and Assistant Surgeon*, to be Major and Surgeon, February 22, 1891.

WILCOX, TIMOTHY E., *Captain and Assistant Surgeon*, to be Major and Surgeon, February 24, 1891.

AINSWORTH, FREDERICK C., *Captain and Assistant Surgeon*, to be Major and Surgeon, February 27, 1891.

HOWARD, VALERY, *Captain and Assistant Surgeon*, to be Major and Surgeon, February 27, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 14, 1891.

KITE, G. W., *Passed Assistant Surgeon*.—Detached from New York Hospital, and ordered to the "Lancaster."

NORTH, J. H., Jr., *Assistant Surgeon*.—Detached from the "Lancaster," and wait orders.

SMITH, G. T., *Assistant Surgeon*.—Detached from the "Independence," and ordered to the "Mohican."

LUNG, GEORGE A., *Assistant Surgeon*.—Detached from the "Mohican," and ordered to Washington, D. C., in charge of insane patients.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MARCH 14, 1891.

LONG, W. H., *Surgeon*.—Granted leave of absence for seven days, March 13, 1891.

AUSTIN, H. W., *Surgeon*.—To proceed to Baltimore, Md., for special duty, March 14, 1891.

GODFREY, JOHN, *Surgeon*.—Detailed as Chairman of Board for Physical Examination of Officer of Revenue-Marine Service, March 4, 1891.

BANKS, C. E., *Passed Assistant Surgeon*.—To proceed to Boston, Mass., on special duty, March 7, 1891.

PERRY, T. B., *Assistant Surgeon*.—Leave of absence extended thirty days, March 13, 1891.

HOUGHTON, E. R., *Assistant Surgeon*.—Detailed as Recorder of Board for Physical Examination of Officer of Revenue-Marine Service, March 4, 1891.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. NOTES ON THE PATHOLOGY OF PELVIC INFLAMMATIONS.[1]

BY A. J. C. SKENE, M.D.,
OF BROOKLYN, N. Y.

WHILE the knowledge of the pathology of pelvic inflammation has greatly advanced in recent times, there is still a wide diversity of opinion among authorities regarding its causation, and the relative frequency with which the several organs and tissues become involved.

This difference of opinion results from a difference in the methods of observation. Some have drawn their conclusions from clinical histories and from physical signs obtained by manual and instrumental exploration; others have made deductions from post-mortem examination; while quite recently a number have based their opinions upon the observations which they have made after abdominal section. To reach the facts requires prolonged and oft-repeated observation from all these points of view. One of the difficulties encountered in the observation, and one which has led to many differences of opinion in regard to the pathology, is that pelvic inflammations seldom come singly. Many of them come together, and so complicate one another that it is impossible to ascertain anything definite regarding the lesions, although investigated in every possible way.

It simplifies the subject and gives more definite results to consider separately the pathology of each form of inflammation which has been found to occur, and then to consider the groups which they naturally and actually form.

I. *Pelvic Cellulitis.*—This was at one time regarded as the most frequent of pelvic inflammations, but recent observations show that it does not take first rank in this respect. Extremists have hinted that it is very rare, and that when it does exist it is secondary to peritonitis or salpingitis. As a matter of fact, it occurs independently of either of these inflammations, and in this respect may be considered a distinct and primary affection. It is generally caused by sepsis, or by gonorrhœal infection derived from the vagina or cervix uteri, and transmitted to the cellular tissue through the bloodvessels or lymphatics; or by contusions of the cellular tissues which cause extravasation and necrosis without any apparent extrinsic infection. These conditions are especially operative in the puerperal state, but may be due to injuries received during surgical operations. Another known cause, although a very rare one, is the rupture of a vessel in the cellular tissue—a pelvic apoplexy. This does not necessarily cause inflammation of a distinctive character, and only does so, perhaps, when the blood is in a morbid state. These are the causes of primary cellulitis.

The course pursued by the inflammation is the same as in cellular tissue generally. It may end in resolution or in suppuration, the size and location of the abscess depending upon the extent of tissue involved. Pus is almost always discharged through the vagina, occasionally through the abdominal wall, rarely through the bladder or rectum. In a few cases the pus has burrowed outward and upward to the sheath of the psoas muscle. If the abscess opens at its most dependent part evacuation and drainage are complete, and recovery is sometimes so perfect that not a trace of the former disease can be found upon examination either during life or after death. This fact has been used as an argument to prove that a cellulitis did not exist.

This is not the invariable history of cellulitis. Suppuration may continue indefinitely, because the evacuation is incomplete and the drainage imperfect, owing either to the location of the opening in the abscess, or to the fact that there is a large mass of inflammatory products honeycombed with small abscesses. In some cases the abscess wall is very thick and is a long time in disappearing after the sac has closed. This leaves a solid mass in the cellular tissue and some fixation of the uterus. This condition is called chronic cellulitis by some, but it bears the same relation to inflammation as do ashes and charred timbers in a building to an extinct fire. Most of the extreme modern pathologists diagnose this condition as tubal, ovarian, or peritoneal inflammation.

II. *Pelvic Peritonitis.*—This occurs as a distinct affection. Its presence alone has been recognized clinically and abundantly demonstrated post-mortem.

The cause of primary peritonitis is sepsis conveyed through the lymphatics which run directly from the vagina and cervix uteri to the pelvic peritoneum. In this respect the causes of pelvic cellulitis and peritonitis are somewhat alike. When there are superficial abrasions of the mucous mem-

[1] Read before the Medical Society of the State of New York, February 3, 1891.

brane, the septic material in the vagina or cervix causes peritonitis, while deeper injuries, like lacerations, are prone to eventuate in cellulitis. This is only a possible explanation of well-known facts.

Among the causes of pelvic peritonitis are:

1. Certain constitutional conditions which predispose to inflammations of serous membranes, the most notable of which are advanced renal disease and tuberculosis.

2. Rupture of a Graafian follicle, presumably having morbid contents.

3. Exposure and excesses.

The relative importance of these is not well established. The fact, however, is known, that inflammations of the pelvic peritoneum and the pleura occur as primary affections when the cause cannot be definitely discovered. Perhaps some pathological state of the blood may be responsible for the predisposition, and some unnoticed slight traumatism may be the excitant.

Secondary pelvic peritonitis will be referred to later. Pelvic peritonitis may be circumscribed or may involve the whole pelvic peritoneum. In the primary form the process, as a rule, ends with transudation and exudation, and rarely does suppuration occur, unless the cause is sepsis of a virulent character, or tuberculosis. If suppuration occurs, or if there is a large serous transudation, the pus or serum accumulates in the sac of Douglas, and is walled-in, if the case does not end fatally, by an exudate which bridges over the sac of Douglas. If the walling-in is complete and protects the subject from fatal septicæmia, the pus is discharged through the rectum in all or the great majority of cases, unless evacuated by the surgeon. Adhesions take place where the inflamed surfaces meet. In mild cases these are generally limited to the abdominal ends of the tubes and their nearest neighbors, and to the most dependent parts of the peritoneum. Recovery follows, but is slow in all cases, and is seldom complete. The structures are more or less damaged by the exudate and adhesions, according to the extent of the disease, and in time the exudate and even the adhesions may be taken care of by absorption. The products of this inflammation have in the past been mistaken for the results of pelvic cellulitis. While they usually cause pain and discomfort and impair the functions of the pelvic organs, they do not tend to a fatal result, and generally yield to prolonged treatment.

III. *Salpingitis.*—This form of inflammation seldom occurs alone. Primary cases are due to tuberculosis, a hæmorrhage or occlusion of both ends of the tube. In the latter condition, the natural secretions accumulate and cause a limited inflammatory process. In the great majority of cases salpingitis is caused by endometritis, either catarrhal or septic. It is sometimes found to exist in the absence of all the other forms of pelvic inflammations which we have considered.

When caused by catarrhal endometritis, salpingitis ends either in recovery or in hydrosalpinx, which may in time excite pelvic peritonitis, or it may, by discharging into the uterus, end in recovery, but leave a more or less damaged tube. Again, it may remain and give trouble until the tube is removed by the surgeon.

When the cause is septic or specific, pyosalpinx usually results. This leads to other and serious complications and has no tendency to recovery, except when after repeated attacks or a single violent one of peritonitis the diseased tube is walled-in above, and, by disintegration of the opposing tissues below, it opens into the rectum or into the cellular tissue, and then finds an exit through the vagina or other pelvic viscera. This does not always terminate the disease. Prolonged suppuration and septicæmia may cause a fatal termination.

IV. *Inflammation of the Ovaries.*—This occurs in a variety of forms, but there are only two which present distinct clinical histories: (*a*) The *acute*, which ends in suppuration, and (*b*) the *degenerative* or so-called *chronic* ovaritis.

(*a*) *Acute ovaritis.* Acute ovaritis is, as a rule, a secondary affection. The causes are puerperal and specific inflammations and neoplasms, and degenerative disease of the ovaries.

Ovarian abscesses found in connection with puerperal metro-peritonitis are familiar examples of the former, and suppurating ovarian cysts illustrate the latter. The termination of ovarian abscess is in death; at least that is the tendency—the abscess rupturing and causing fatal shock or peritonitis. The exceptions to this are when relief is given by the surgeon, before or at the time of rupture, and when the ovaritis sets up peritonitis before rupture and the ovary becomes walled up in the sac of Douglas. The abscess may also discharge through some of the pelvic viscera or be reached through the vagina or by abdominal section.

The important point to be observed in the pathology with reference to treatment is that there is a difference between those cases in which the diseased ovary is lodged in the sac of Douglas and walled-in by protecting exudate, and those that are not so guarded. This difference should determine whether the interference of the surgeon is to be immediate or delayed.

(*b*) *Chronic ovaritis.* This is characterized by histological changes rather than by the development of the products of ordinary inflammation, and is a very common affection. It has been claimed that it is caused by endometritis, the assertion being based upon the similarity of structure of the

endometrium and the ovarian tissue, and the fact that endometritis and this form of ovaritis usually coexist. Much might be said on this point, but time only permits me to add that this method of causation is not proven. As nearly as can be ascertained the cause is malnutrition, giving rise to certain degenerative changes, which in their pathological histology bear a much closer resemblance to hepatitis and nephritis than to the products of inflammation in connective tissues and in serous and mucous membranes. The ovary is peculiar in this, that each performance of its function entails a certain irreparable destruction of a portion of its tissue. It is an organ that is continually degenerating during its functional activity, and hence it is difficult to find the line of demarcation between the physiological destruction of tissue and the pathological changes which occur from inflammation—difficult, I should say, to all but those who have a proclivity to remove ovaries. Surgeons of that tendency find evidences of disease with a facility which startles skilled pathologists. Ovaritis of this form, in an ovary that is not displaced, does not tend to fatal results, and hence does not call for ovariotomy. In many cases the degenerative changes in structure lead to atrophy, arrest of function, and the disappearance of all symptoms. Such atrophied ovaries are supposed to be the site of neuralgic pain, which is so violent and persistent as to call for extirpation. This is not invariably the condition which causes pelvic pain, if we may judge from the fact that removal of degenerated ovaries does not always give relief.

Any of the inflammations here referred to may lead to one or to all the others—that is, the one, instead of running its course alone and uncomplicated, may excite secondary inflammation in any of the other organs or tissues. But either of them may occur alone, and they all may occur in succession, and even coexist.

Cellulitis often leads to secondary peritonitis, while peritoneal inflammation rarely extends to the cellular tissue. When such an extension occurs it is usually from burrowing of pus that has become walled-in, forming an abscess in the sac of Douglas. This takes place late in the progress of the disease and is sometimes considered a recurrence or relapse of the peritonitis. Along with the acute symptoms, which are lighted up by the burrowing of pus, come the physical signs of the cellulitis. When suppuration takes place in the cellular tissue it is often diffused and does not present a well-defined pus sac as in primary cellulitis.

Peritonitis frequently damages the ovaries and outer ends of the tubes, but it is seldom that a general inflammation of either is caused by peritonitis. When all of these coexist, inflammation of the tubes and ovaries occurs first, as a rule.

Looking at the subject as a whole, there are a few well-defined facts. The first of these is, that no matter where inflammation begins or what parts it involves, if the process gives rise to the formation of pus, the pus must be removed by the surgeon either through the vagina or by laparotomy in the majority of cases. Still another fact worthy of mention is, that in case the inflammation subsides before suppuration occurs, the resultant lesions are rarely improved by operative surgery—they do best upon general treatment.

By way of making more clear the foregoing statements in regard to the pathology, a word may be said about the lesions which remain or which may develop after laparotomy. The adhesions which surround a tube filled with pus and need to be broken up or divided in order to remove the tube, reunite, and more adhesions form. This is inevitable and must be tolerated; but when a laparotomy is done for the purpose of diagnosis or to remove an inflamed organ which is presumed to be offending, the lesions are seldom improved, and the suffering is not rendered less bearable to the patient.

FORCIBLE INTERMITTENT TRACTION IN THE TREATMENT OF CLUB-FOOT.[1]

By NEWTON M. SHAFFER, M.D.,
Attending Surgeon in Charge of the New York Orthopædic Dispensary and Hospital; Consulting Surgeon to St. Luke's Hospital, New York.

The phrase "forcible intermittent traction" is intended to describe a simple but effective operation for reducing certain non-inflammatory chronic deformities, which the author of this paper introduced to the medical profession in the New York *Medical Record* for November 23, 1878, in a paper entitled "Traction in the Treatment of Club-foot." The subject was further amplified in a paper on "Knock-knee and Bow-legs," published in *The American Journal of Obstetrics and Diseases of Women and Children*, in July, 1881.

The operation, which was referred to in the papers mentioned as "an exaggerated momentary pressure," is based upon the tolerance of the skin and subcutaneous tissues to a very great degree of pressure for a brief period of time, and it is further based upon the well-known law that in order to remove a given obstacle the "force must exceed the resistance." The chief causes which led to the application of these two principles to the reduction of chronic deformity were especially the imperfections in the

[1] Read before the Orthopædic Section of the Tenth International Medical Congress, held in Berlin, August, 1890.

conventional apparatus for the treatment of club-foot, and the unsatisfactory results that followed their use.

The first thing that I strove to accomplish was to devise an apparatus which could be made to fit any ordinary club-foot at will, with the mechanism so arranged that when the initial force was used it could be directly applied to the resisting tissues. In short, I endeavored to imitate the action of the trained human hand when applied to the reduction of the deformity, and in all of the instruments here described it would seem that not only this object, but even more, has been accomplished, when one estimates the degree of force which the human hand is capable of applying and compares it with that exerted by the apparatus here described.

In using forcible, intermittent traction for the reduction of the deformities of talipes, either with or without tenotomy, myotomy, or syndesmotomy, the apparatus is so arranged that the pressure may be carried up to a point of educated tolerance by gradually increasing pressure, and as soon as the patient indicates that a maximum pressure is reached all force is to be *instantly removed*. If the apparatus is properly adjusted, each forcible traction will be followed by a yielding of the deformity, and if it is applied frequently and systematically, the improvement will soon be very noticeable. If the deformity fails to yield after a sufficient trial, a free subcutaneous section of all the easily reached muscular and fibrous tissues will so modify the resistance that the condition will be a formidable one which does not then yield to this force.

In an article published in the New York *Medical Journal*,[1] March 5 and 12, 1887, I gave some directions for the use of forcible intermittent traction in the treatment of club-foot. Time has demonstrated their general correctness, and I reproduce them here with such modifications as experience suggests.

The first step is to adjust the apparatus *so that it will exactly fit the deformity*. Determine at the first application how much traction can be tolerated by the patient without causing pain. Proceed easily and gently at first, and after a few applications the traction may be increased to any desired extent without difficulty. After the patient is accustomed to the apparatus, keep the traction-shoe applied the greater part of the day, using a simple retention, walking, or a night, apparatus at all other times. By this means the foot will not be permitted to relapse into its former position of extreme deformity.

When the patient learns that he can control the amount of traction, commence a systematic application of the forcible intermittent traction.

The traction should be applied every fifteen or thirty minutes for the period of educated tolerance, be it for one second or five minutes. Patients vary greatly in their ability to bear the pressure, but all may be educated very soon to endure a sufficient degree of pressure to make "the force exceed the resistance" to an extent which shows an appreciable gain in a short time. Experience proves that what is gained during the seconds or minutes of forcible traction is not wholly lost during the period of intermission, and during the latter time the patient may walk about in the traction apparatus, which is adjusted to an easy position with a minimum pressure.

If these rules are followed there will soon be found a lengthening of the plantar tissues, and the gastrocnemius will become visibly longer. In the average case the shortened tissues will yield without the use of the knife; but in some cases, after a few weeks of forcible traction, the resisting tissues seem to yield no further—or, yielding, will, like an elastic cord, gradually shorten soon after the traction is removed. As soon as it is demonstrated that this is the case, all the resisting muscular and fibrous tissues should be divided subcutaneously, when it is probable that one prolonged traction under anæsthesia will remove the deformity.

Excoriations are not likely to occur, and if suitable precautions are taken they do not occur at all. The only case of troublesome excoriations that has happened in my own experience resulted from a too prolonged traction after operation and under anæsthesia.

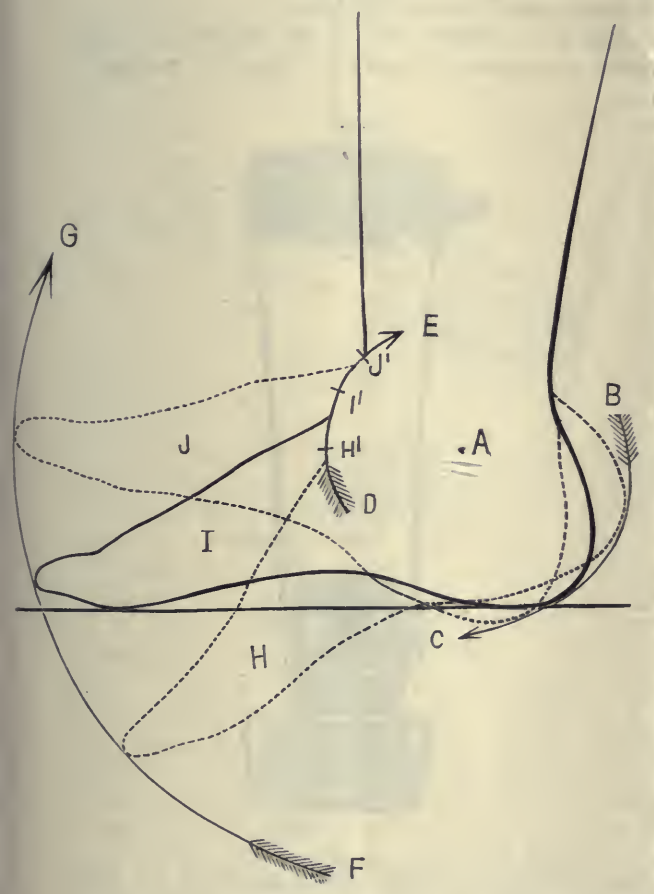
In using forcible traction without tenotomy, etc., I instruct someone interested in the patient in the use of the apparatus, so that treatment may be carried out at home. This is always very easily accomplished in private practice. The pain inflicted by properly applied forcible traction is so slight that neither the patients, if they are children, nor their parents complain. Adolescents and adults bear it without any complaint whatever.

The question will at once be asked, "What is the length of time required to secure a good result by the use of this method?" My answer is, that if subcutaneous section and forcible traction are used as the initial procedures, the reduction of the deformity can be ordinarily accomplished at one sitting during the anæsthetic stage of the operation. But if a preliminary trial of traction is made, and if the conditions favor its use to the exclusion of tenotomy, etc., the treatment will probably require six months or a year. As is well known, it does not do to dispense entirely with treatment after the simple reduction of the deformity by operation. An apparatus must still be worn, and all that is ordinarily gained by the cutting operation is the immediate reduction of the deformity. At the end of a

[1] "The Use of Traction in the Treatment of Club-foot."

year the patient who persists in the traction treatment alone will have a much better foot than the one which is subjected to the cutting process. When time is of importance, as it is among some dispensary patients, the rapid process should be employed. When, on the contrary, time is not so important an element, and when the best attainable result is desired by the patient or his parents, it is well to use the forcible traction alone until it is demonstrated that the result cannot be obtained by this means. And when it is stated that several obstinate cases, which were condemned to osteotomy—or amputation—have been cured by forcible traction alone, and without the aid of the knife, it will be seen that forcible traction promises a great deal.

FIG. 1.



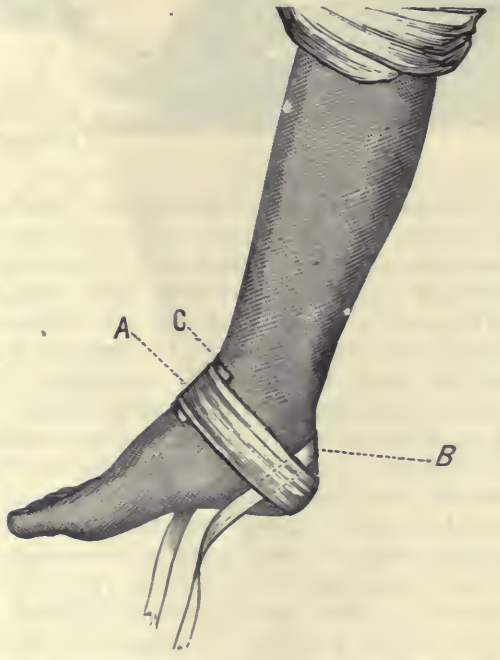
Three forms of apparatus are used: one for the reduction of simple equinus, known as the "antero-posterior traction-shoe;" and two for the reduction of equino-varus: one known as the "internal lateral traction-shoe," and the other as the "external lateral traction-shoe."

I will briefly describe these instruments, calling attention to the antero-posterior apparatus first.

The centre of antero-posterior motion at the ankle follows an imaginary line which touches the lower end of the external malleolus, and passes out below the internal malleolus. When the ankle is flexed or extended, motion takes place upon this transverse axis. (A, Fig. 1.) If we study the diagram (Fig. 1) further we will see that A, I, shows the foot in the right-angled position—*i. e.*, with the sole of the foot forming an angle of 90° with the leg; A, H, shows the foot in extreme extension, the sole of the foot being at an angle of about 135° with the leg. A, J, shows the foot in extreme flexion, the sole of the foot forming an angle of about 70° with the leg.

The position of the foot in talipes equinus is represented by the position A, H, and the object of treatment is to carry the foot from A, H, to the position A, J. The whole foot rotates upon the centre A. Hence the heel must describe the arc of a circle represented by the curved arrow, B, C., and it will be noted that the direction of this curve is *downward* and *forward*. The toes, also, rotate around the same centre, and in passing from H to J they follow the curved arrow, F, G, the direction of which is *upward* and *forward*. The head of the astragalus lying *above* the centre of motion A, (the heel being below the centre) must move in a direction opposite to the heel. The head of the astragalus follows the direction of the curved arrow D, E, its direction being *upward* and *backward*.

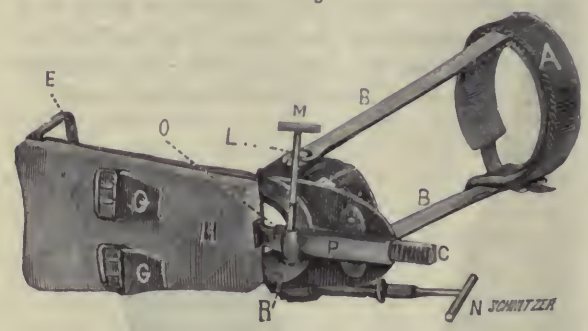
FIG. 2.



In the conventional forms of club-foot shoe for the treatment of talipes equinus a strap is passed over the neck of the astragalus, and in this way the

heel is secured in the heel-cup of the apparatus. When an attempt is made to flex the ankle, the upward movement of the head of the astragalus is at once arrested, and the heel slips beyond the control of the apparatus. Anything which interferes with the *descent* of the heel, or with the *ascent* of the head of the apparatus at once interferes with flexion of the ankle. My first step, after having recognized the mechanism of the antero-posterior movement of the ankle, was to apply a "traction heel-strap" (see Fig. 2, B), which passes over the heel, and is then secured to the *anterior* part of the foot-plate of the apparatus (B, Fig. 5). By this means the heel can be absolutely kept in its position—*i. e.*, it can be held securely, and prevented from rotating *upward* and *backward* away from the apparatus. But this did not fully meet the conditions. The tight astragalus strap still prevented the *upward* movement of the astragalus. The next step was to divide the foot-plate of the apparatus transversely at a point corresponding with the medio-tarsal joint, and to connect the *heel* part with the *tarsal* part by a traction-rod. (Fig. 3.) We are now enabled to loosen

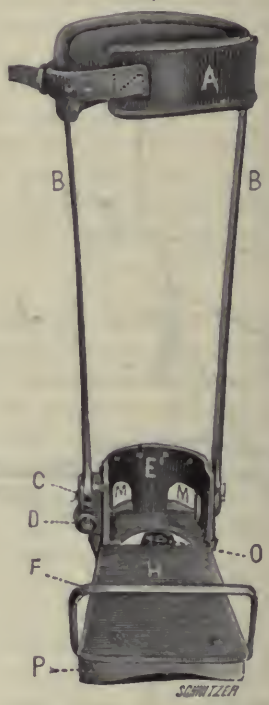
FIG. 3.



the astragalus strap after adjusting the apparatus and securing the heel traction-strap, so as to permit the upward movement of the head of the astragalus —while we can forcibly draw the heel *downward* and *forward* by the long traction-rod. Then another difficulty presented itself. The heel part of the foot-plate prevented the descent of the heel. For some time the reason for this was not plain, but it is explained in this way: as soon as considerable resistance is met with in bringing the heel downward and forward, the centre motion at A (Fig. 1) becomes blocked, and the centre of motion, upon which the heel is passing downward and forward, is transferred from A (Fig. 1) to the upward and backward rotating astragalus (H', I', J', Fig. 1), which is held in position by the strap already referred to. The heel, therefore, moves downward and forward upon a radius more than twice that of an unopposed movement in the normal ankle, and descends much more rapidly than the foot-plate of the apparatus, which has a transverse centre corresponding with the normal axis of rotation. The next step was, therefore, to remove the heel part of the foot-plate, and the result is the apparatus shown in Figs. 3 and 4. Fig. 3 is a view of the lower part of the foot-plate. The buckles, G, G, for the attachment of the traction heel-strap; the traction-rod, C; the cylinder, P; the flexion and extension worm and screw controlled by the key, M, are plainly shown. The key, M, is in position to throw the anterior part of the foot-piece forward. The opening, O, for the descent of the heel, in the foot part of the heel-cap, surrounded by its strong rim, R, is also shown. When traction is made, and the heel is brought downward and forward, it passes through this opening unopposed by any obstruction.

Fig. 4 is another view of the apparatus. The worm and screw are shown at C and D; the heel-

FIG. 4.



cup at E, with the two openings, M, M, for the astragalus retention-strap; the opening, O, for the descending heel, and the bridge, F, for the reflected heel traction-strap.

Figs. 5, 6, and 7 show the detail of the action of this apparatus. In Fig. 5 the apparatus is adjusted to fit the deformity, the astragalus retention-strap, A, and the heel traction-strap, B, being in position. In Fig. 6 the apparatus has been carried by the key from the position of extension to the right-angled position, the foot still remaining, however, in its

FIG. 5.

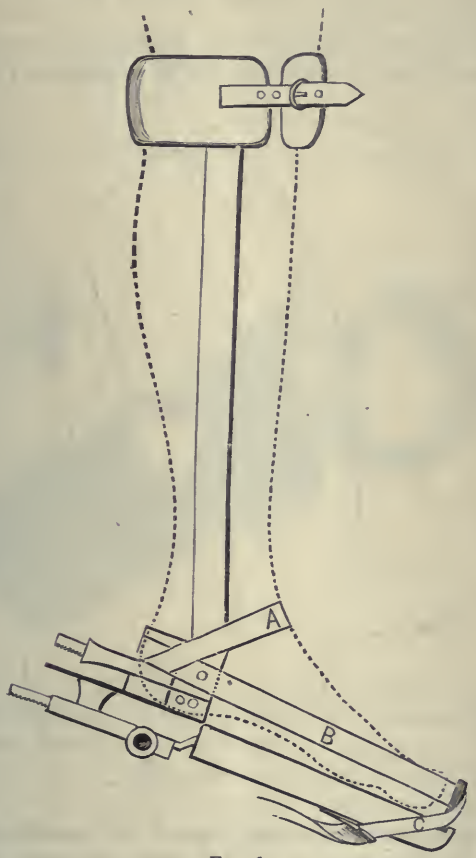


FIG. 6.

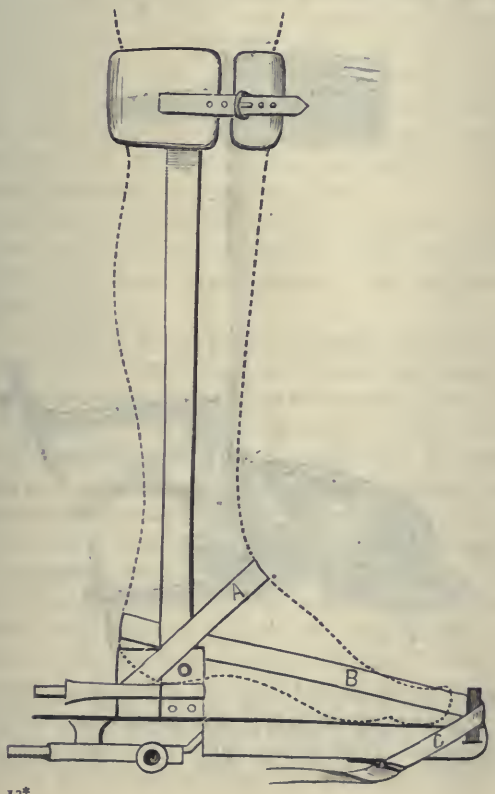
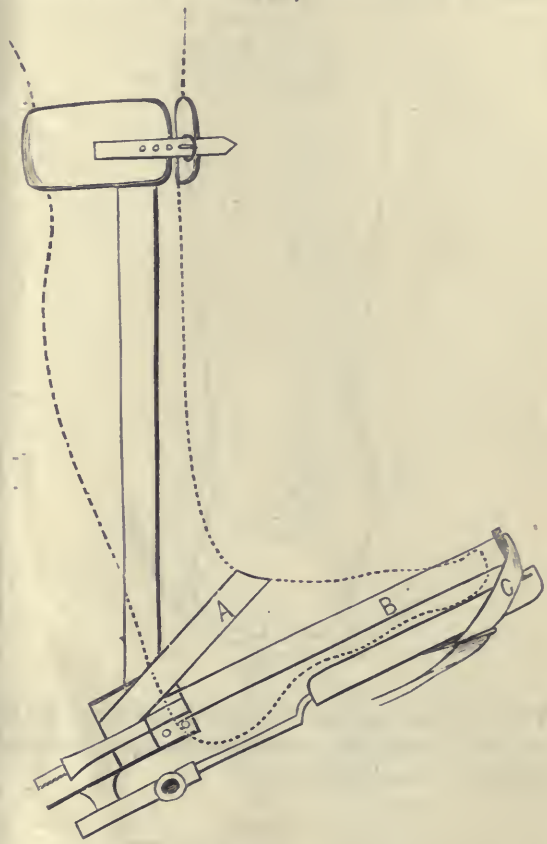


extended position. The apparatus has changed, but the foot has not. In Fig. 7 the apparatus has been

FIG. 7.



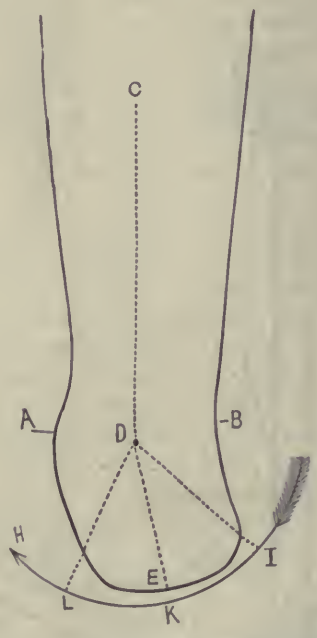
placed by the key in a position of flexion, and the traction-rod has been used to throw the foot-plate forward.

The heel, which must follow this movement, has been drawn downward and forward into the desired position.

The force that can be applied by this apparatus is practically unlimited. Many cases of obstinate club-foot have yielded to this apparatus alone. The force can be applied with mechanical exactness at the desired points, and a very great degree of traction is exerted upon all the tarsal joints, as well as upon the post-tibial tissues. Under anæsthesia and with free subcutaneous division of the tendo Achillis and the plantar fascia it can be made to do very efficient service in desperate cases; while in ordinary cases of club-foot, in which there is a residual resistance after free subcutaneous incisions, there is little or no difficulty in removing the deformity, provided the lateral displacement of the tarsus does not prevent the application of a strictly antero-posterior force. If the "lateral deformity" of the tarsus be considerable, one of the lateral instruments should be used.

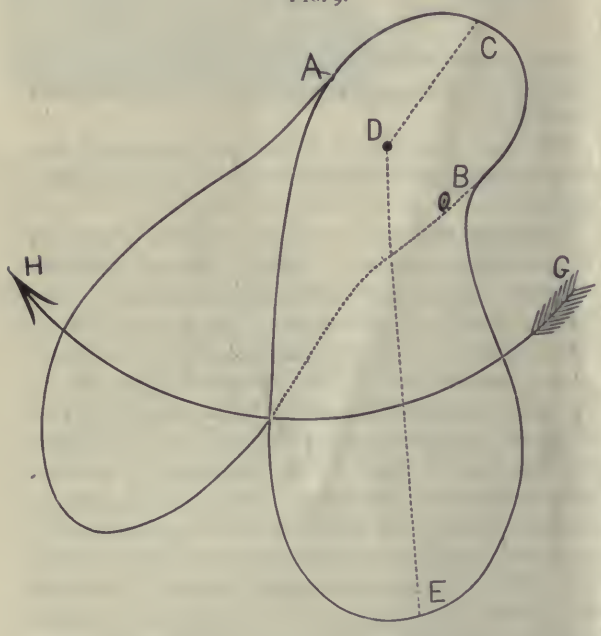
The internal lateral traction shoe will now be described. This apparatus is a *pusher*, being applied to the *concave* side of the deformity. Its general outline and appearance is shown in Figs. 11 and 12.

FIG. 8.



This and the external lateral traction shoe are the results of much study and experiment, to the details of which I need not refer.

FIG. 9.



The deformity of equino-varus is a very complex one. The tarsus is rotated upon three axes: first, upon a transverse axis (equinus); second, upon an antero-posterior axis (Fig. 8); and third, upon a vertical axis (Fig. 9).

In order to meet all these indications, an apparatus should be constructed so as to produce a lateral pressure in the direction of the curved arrow (I, H, Fig. 8), and also in the direction of the curved arrow (G, H, Fig. 9), the heel being controlled and the equinus antagonized by the traction heel-strap, as shown in Fig. 7. The centre of

FIG. 10.

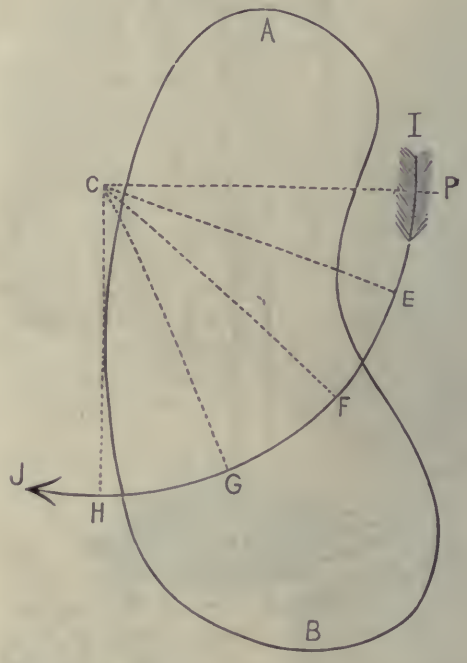


FIG. 11.

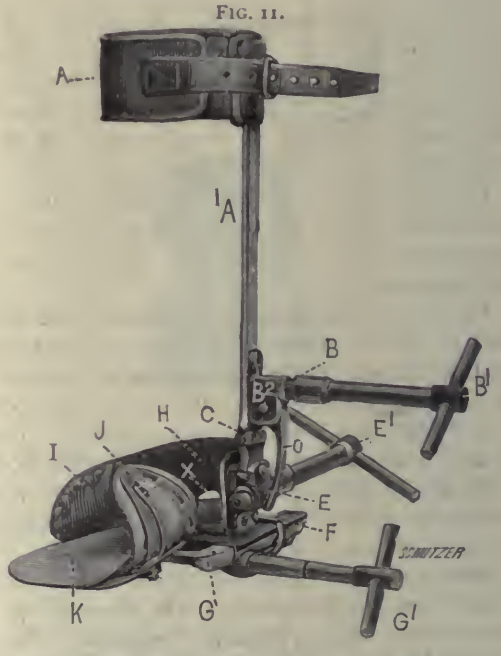
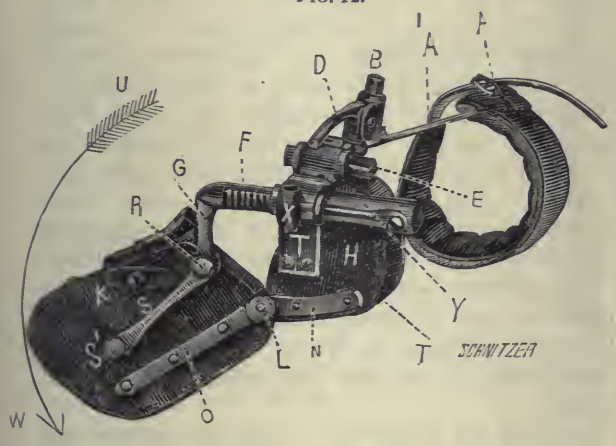


motion for pushing the os calcis toward a straighter position (downward or outward) cannot be located in the internal lateral apparatus at the point indicated (D, in Fig. 8), so it is placed at the point B (Fig. 8). The centre of motion for the deformity which occurs on a vertical axis should be

Fig. 12.



located at the point C (Fig. 10). This being understood, we may now describe the apparatus. The inside lateral pusher is shown in Figs. 11 and 12.

In Fig. 11 the key B′, acting on a hinge at C, throws the hinged lever and screw O toward the rotated heel. The key E′ raises the toes by a worm-and-screw movement at E, while the key G′ throws the anterior part of the foot *forward* and *outward*, as shown by the centre C (Fig. 10) and by the centre L (Fig. 12). There is an open heel-plate for the descent of the heel upon the rotating astragalar centre, and the traction heel-strap, as well as the retention astragalar strap, is used as in the antero-posterior traction apparatus.

This apparatus is particularly applicable to obstinate cases of equino-varus, where the resistance is principally in the plantar tissues and in the gastrocnemius muscle.

The external lateral traction apparatus is devised to meet a class of obstinate cases in which the resistance exists principally in the internal lateral ligament of the ankle-joint and in the ligaments of tarsal bones. This apparatus has not been engraved in detail. Its action can, however, be illustrated by the accompanying diagrams (Figs. 13 and 14), which will explain its mode of action, and will at least suggest the powerful leverage it is capable of exerting. The apparatus is applied to the *convex* side of the deformity and acts as a *puller*. The sketch (Fig. 13) shows in outline the principle involved. The apparatus here shown is intended for the outside of the left foot and leg in a case of equino varus. The bar, H, passes downward in a line which corresponds with the fibula and terminates in an antero-posterior hinge. Connected with this hinge is a *retraction-rod*, E, which when used with a key at its opening,

Fig. 13.

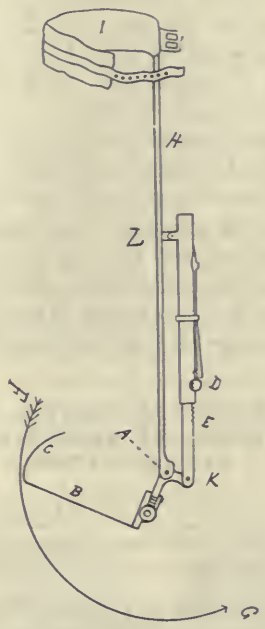


Fig. 14.

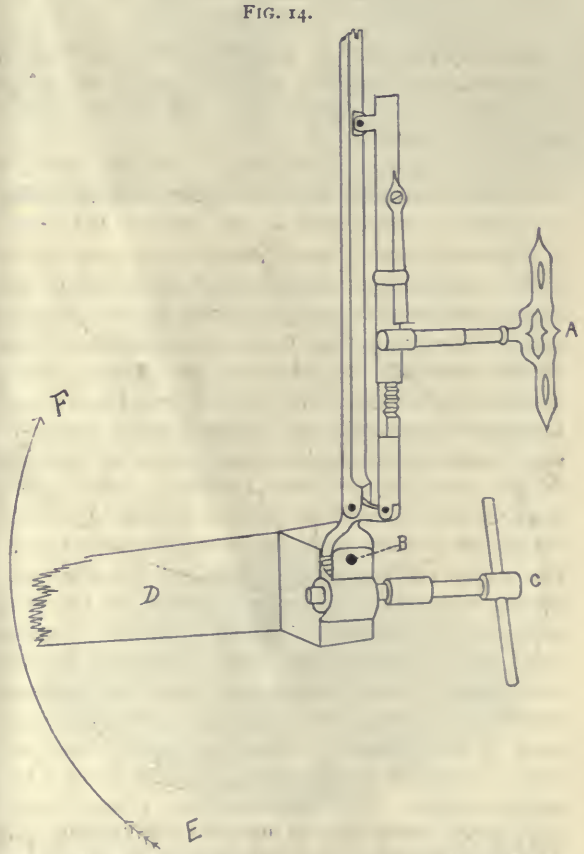

D, carries the distal part of the apparatus *downward* and *outward* upon the centre A in the segment of

a circle indicated by the curved arrow F, G. Of course, it would be useless to apply this *outward* and *downward* movement unless the heel is restrained. This is accomplished by the traction heel-strap (as in Fig. 2), and by means of the worm and screw shown at B, Fig. 14, which, when used by key C, places the foot-piece, D, at any desired point between E and F.

Each of these instruments represents the principle named in the title of this paper, viz., forcible, intermittent traction, and each instrument has produced results that are more than satisfactory. The principle involved may be amplified and an osteoclast can easily be constructed upon the principles here enumerated, so great and so easily controlled is the force developed by the mechanism described.

A CYSTIC MYOMA OF UNUSUAL CHARACTER TREATED BY ELECTRICITY AND ASPIRATION.

BY G. BETTON MASSEY, M.D.,
PHYSICIAN TO THE GYNECOLOGICAL DEPARTMENT OF HOWARD HOSPITAL AND TO THE DISPENSARY FOR THE TREATMENT OF THE DISEASES OF WOMEN BY ELECTRICITY.

THIS case is worthy of a special report because of the peculiar and most painful swelling of the tumor at stated periods. It has also taught me that a myoma may require an entirely different method of electrical treatment from a fibroma, and that a cystic degeneration of a myoma is no bar to its successful electrical treatment.

When first seen there was a nodular mass of irregular consistency filling the pelvis and extending to within three-fourths of an inch of the navel. The greatest lateral breadth was five and one-quarter inches, including a process that extended to the right from the main portion of the tumor. Examination showed the mass to be an interstitial uterine tumor involving the whole of the organ, with a special projection to the right. The lady, who was forty-seven years old, had suffered seven years with this trouble, which began three years after the birth of the youngest of three children. During this time, at each recurring menstrual period, she would be thrown into an attack of severe illness and pain, the tumor swelling until it touched the ribs, producing a profound disorganization of all the vital activities by suddenly applied pressure. Though there was no general peritonitis, the stomach, bowels and kidneys refused to act, and the patient suffered continuously from paroxysmal pain until the appearance of the menstrual flow. At these times the tumor increased to four and five times its size between attacks. The measurements I have given were taken at the time of the patient's admission to my sanitarium, December 3, 1889, and were smaller than they had been for several months. There was no history of hæmorrhages or discharges of any kind, which I think is characteristic of myomata, and the menstrual flow was scant and somewhat irregular.

Treatment was begun by the Apostoli intra-uterine method, and at the end of a month the patient was in a greatly improved condition. This, however, did not last long, for there was a perceptible increase in the size of the tumor in January, 1890, with other signs of an impending attack. No attack occurred, nevertheless, until the following April, but I was greatly disappointed at the obstinate refusal of the tumor to decrease in size, which I am now sure was due to the irritation caused by too frequent intra-uterine applications in an œdematous myoma. The applications were generally made every other day, but caused such painful spasms of the uterine mass that the current strength was kept between forty and seventy milliampères. Each pole was used at different times. The result was simply to postpone the attack, which came on with great force in April, after the cessation of the treatment.

During the following summer the patient had several severe attacks, the tumor failed to go down to the size usually maintained between attacks, and the patient, much reduced in strength, was further troubled with œdema of the right leg. Rejecting my advice that an operation be performed before the appearance of another such attack as I had witnessed, the patient and her friends urged the continuance of electricity until its various methods had been thoroughly tried. I, therefore, began the use of a method which I have since learned is similar to that of Damion, of Paris, namely: vagino-abdominal galvanic alternatives. The Apostoli clay pad was used in the usual position, and for the active pole a cotton-covered carbon electrode in the vagina pressed well up against the growth. By this method 150 milliampères were readily turned on without discomfort, the current being decreased, reversed, and again turned on without shock by means of the controller. This was repeated six times at each sitting.

This method of treatment, which has been in my experience usually ineffective in hard fibroids, gave immediate results in this soft muscular growth, ameliorating the symptoms and gradually effecting a decrease in size. Recognizing the contractile nature of this growth, I began also to apply strong primary faradic currents to it through the thin abdominal walls, the active electrode being the size of the hand, with a large dispersing electrode on the back. The relief this caused was always immediate though doubtless temporary, for a three-minutes application of a gradually produced strong current caused a diminution in the size of the right wing of the tumor that was plainly perceptible to both sight

and touch. As, however, but little permanent reduction was occurring, a more thorough examination was made, disclosing the presence of several cysts of considerable size in the right extension of the growth. The patient was at once readmitted into the sanitarium and the largest cyst aspirated through the abdominal wall, two ounces of a clear, straw-colored liquid being drawn off. After a microscopical examination the liquid was pronounced by Dr. W. M. L. Coplin to be from a degenerating myoma, and contained many broken-down blood-corpuscles. After this procedure, and after each of five subsequent aspirations of different cysts, the tumor showed a continuous decrease, the contractions produced by the current becoming permanent. The electrical treatment by the modified method was continued for several months, but owing to the patient living some distance from Philadelphia the applications could not be made oftener than once per week. The tumor, which is now no larger than a small orange, is continuously decreasing in size, and has for some four months passed out of the life of the lady, who is no longer conscious of it unless reminded of its presence by others. She is in the enjoyment of perfect health and appears at least ten years younger than when I first saw her.

I have given the exact details of this case because it has been already partially reported by me as an electrical failure, in a discussion before the American Association of Obstetricians and Gynecologists in September, 1890. In the sequel, as seen, it is by no means a failure, and illustrates most admirably the denutritive and contractile power of dense interpolar action, while at the same time warning us of the inefficiency of intra-uterine galvanic applications in myo-cystic growths, in spite of their great value in ordinary fibroids.

In reviewing this case at a period of time sufficiently remote to permit of an accurate estimation of results, I cannot refrain from a feeling of satisfaction that they were obtained without the patient passing through an operative shadow of death, without mutilation, and with an abdominal wall that will remain free from the possibility of a future hernial weakness.

IMPROVED EYE-PADS FOR THE AFTER-DRESSING IN CATARACT OPERATIONS.

By L. WEBSTER FOX, M.D.,
of Philadelphia.

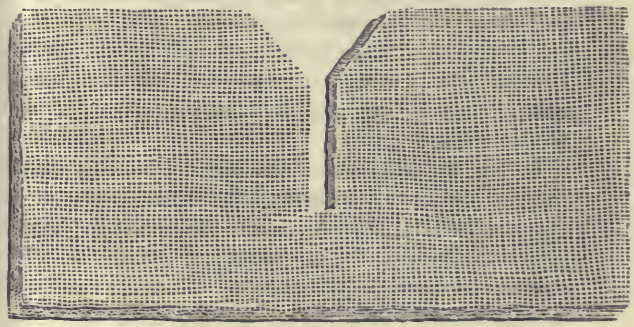
The after-dressing in cataract operation is a very important factor in its successful termination. Prior to the days of Von Graefe very little or no dry dressings were applied in the after-treatment in ophthalmic operations.

Before that day the lids were held in place by adhesive plaster or simple bandages. Von Graefe, however, changed this mode of after-dressing, and his followers have tenaciously adhered to his iron-clad rules ever since.

Several years ago Dr. Michel, of Charleston, and Dr. Chisolm, of Baltimore, revived, as they called it, the "rational method" of after-treatment in cataract operations, simply using adhesive-plaster dressings. In the light of our present knowledge of aseptic surgery there are many who still follow the rules given by Von Graefe.

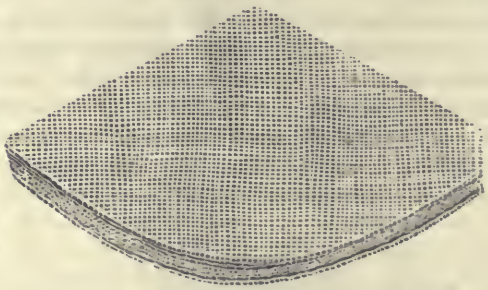
Every ophthalmic surgeon has his own peculiar way of applying a dressing to an eyeball. Patent lint and aseptic absorbent cotton held in place by a bandage constitutes this dressing. I have used such a dressing for the past ten years and the results obtained have been all that could be desired. The preparation of eye dressings has always taken considerable time and their adjustment is not always satisfactory.

Fig. 1.



The eye-pads now used are of two kinds, black and white, and are made as follows: First, a lining of antiseptic gauze, then a layer of absorbent cotton, next the black linen sheet, and lastly, the white gauze for the external covering. The size of the pad is six and a half by three and a half inches. The white pads (Fig. 1) are made in like manner, omitting the black linen, all hydronaphtholated.

Fig. 2.



The smaller pads fit closely over the eyeballs (lids closed), the material being identical with that of the

larger ones. Both large and small pads are shaped and cut by a steel die. They fit comfortably and evenly to the face, being held in place either by adhesive strips or a knitted bandage. I am indebted to Messrs. Seabury and Johnson for carrying out my suggestions in the making of these eye-pads.

THE ASEPTIC METHOD AS APPLIED TO INTRA-NASAL SURGERY.[1]

BY JOHN O. ROE, M.D.,
OF ROCHESTER, N. Y.

No medical or surgical procedure has shown a more remarkable growth than the antiseptic method as applied to the treatment of wounds—a method which has created a new epoch in the art of surgery, and has made immortal the name of its first scientific expounder.

In the earliest application of this method the primary object was to destroy the noxious germs which infest the wound and which obstruct the healing of the part by the putrefactive or fermentative processes due to their presence. This early procedure, which may be regarded as strictly antiseptic in its character, has gradually given way to the method of asepsis, the purpose of which is to prevent the infectious germs from gaining entrance to the wound.
